Abstract

We examine the employment responses to import competition from China and to global export expansion from the United States, both of which have been expanding strongly during the past decades, particularly from 1991 to 2007. We find that although Chinese imports reduce jobs, at both the industry level and the local commuting zone level, the global export expansion of US products also creates a considerable number of jobs. On balance over the entire 1991-2007 period, job gains and losses due to changes in US global exports and Chinese imports were roughly balanced in the industry data. When aggregating to commuting zones, however, we still find that jobs reduced due to Chinese imports exceed jobs created due to US exports, by slightly less than one million manufacturing jobs. In future work we will expand our analysis to include exports from agriculture and services and employment in these sectors.

1 Introduction

Conventional wisdom in economics is that trade liberalization will have two effects on labor market outcomes. On the one hand, firms that face import competition may shrink or even exit and therefore displace workers. On the other hand, firms that gain access to foreign market should enter or expand, therefore generating numerous new jobs. Although such effects of job creation and destruction due to international trade are commonly accepted, empirical studies, particularly the recent growing literature on the 'China shock', focus on the job reducing effect of surging imports from China or other low-wage countries on the US labor market (Autor, Dorn, and Hanson, 2013; Pierce and Schott, 2016; Acemoglu et al., 2016).[1]

This paper aims to fill this research gap by providing the first account of the job creation due to the export expansion in the United States, at both the industry level and the local labor market (commuting zone) level. The United States is one of the leading exporting countries in the world trading system: in 2014, the value of its merchandise exports reached more than 1.6 trillion US dollars, second only after China. Figure 1 presents the export growth for US aggregate merchandise exports and manufacturing exports from 1991 to 2011. It shows that prior to the global financial crisis, US exports grew strongly, from less 600 billion (in 2007 US dollars) in 1991 to more than 1.2 trillion dollars. No doubt such expansion in export value would generate increasing demand for labor. The US export expansion is certainly not evenly distributed across industries, however. Figure 2 lists the top industries that have experienced the largest increase in exports during 1991 - 2007. Among 392 revised SIC manufacturing sectors, semiconductors experienced the largest increase in export value during 1991-1999, while motor vehicles and petroleum refining have been the champion of export expansion in the period 1999-2007.[2] These top categories reflect America's comparative advantage, and grow much faster

[1] A notably exception is Dauth, Findeisen, and Suedekum (2014), who employed the German trade and labor data to show that the rise of the East (Eastern Europe and China) caused substantial job losses in regions exposed to import competition, while it also led to strong employment gains in regions that are more export oriented.

[2] As a comparison, Figure 3 presents the top import SIC categories that have experienced the largest increase in volume from China.

than many other categories, some of which even saw reductions in exports, therefore creating large variations for our empirical identification.

[Figure 1 & Figure 2 & Figure 3 about here]

Empirically, however, it is not easy to have an unbiased estimation of the export expansion due to endogeneity. While increased access to foreign markets drives up demand for labor employment, domestic supply shocks such as new technology or TFP growth will promote exports, causing difficulty in indentification. Uncontrolled (often unobserved) domestic shocks, such as demand shocks, may affect export growth and labor employment simultaneous, thereby creating omitted variable bias in estimation. Lack of plausible instruments probably explains the lack of more balanced empirical evidence of the effect of both export and import shocks on employment.

To deal with endogeneity, we adopt two instuments. First, we follow the spirit of Autor, Dorn and Hanson (2013, henceforth ADH) to look at the export expansion of other high-income countries.[3] This is based on the assumption that these high-income countries face similar import demand shocks from other countries as does the United States. The second instrument that we adopt in this paper relies on the fact that in recent decades, substantial trade liberalization has occured in the form of tariff reductions, particularly for emerging and developing countries. Thus, we contruct a second instrument as the predicted US exports based on the tariffs that US exporters face, the tariffs that other competing countries face, and the rising foreign demand for imports of commodities (except from the US).

Our empirical results show important job gains due to US export expansion. Based on the industry level estimation, our results show that US export expansion *net of* China's import penetration actually led to a net gain of 525,000 jobs in the first period 1991-1999, while it led to a net loss of 520,000 jobs for the second period 1999-2007. On balance over the entire 1991-

[3]ADH (2013) instrument the US import penetration from China using eight other high-income countries' import penetration from China.

2007 period, therefore, job gains and losses due to changes in US global exports and China's imports were roughly balanced.

To account for effects of reallocation and local demand in general equilibrium, we also explore the variations across US commuting zones in their exposure to export and import. We reach somewhat bigger effect of job creation and reduction of trade exposure. Quantitatively, accounting for local market effects implies increased import exposure had led to a loss of about 2.73 million manufacturing jobs in local labor market from 1999 to 2007, and another 1.03 million manufacturing job losses from 1991 to 1999 . On the other hand, increased export exposure implies a gain of 1.7 million manufacturing jobs from 1991 to 1999 and 1.12 million from 1999 to 2007. In net value, export exposure significantly offsets the reduction in jobs caused by import penetration, resulting in about 0.9 million net job losses.

The rest of the paper is structured as follows: Section 2 presents the empirical strategy and describes our main datasets. Section 3 shows the main industry level estimations. Section 4 examines the impact of trade exposure at the commuting zone level. Section 5 continues to lay out a research agenda on US exports in non-manufacturing goods such as agriculture, and in services. Section 6 concludes.

2 Empirical Strategy

We take an approach similar to Acemoglu et al. (2016), investigating the effect of export growth and import exposure on labor employment first at the industry level, and then at the local labor market level.

2.1 Measuring Trade Exposure

Acemoglu et al. (2016) measure the change in the industry level import penetration in the US from Chinese imports as

$$\Delta IP_{st} = \frac{\Delta M^{UC}_{s,t}}{Y_{s,t_0} + M_{s,t_0} - E_{s,t_0}}, \tag{1}$$

where s denotes 392 manufacturing sectors at SIC classification. $\Delta M_{s,t}^{UC}$ denotes the change in *US imports from China* (UC) in sector s for the time period t (t is either 1990-2000, or 2000-2007, and in some cases 2000-2011). To normalize, $\Delta M_{s,t}^{UC}$ is divided by the initial domestic absorption, which consists the industrial real shipment, Y_{s,t_0}, plus industry real net imports, $M_{s,t_0} - E_{s,t_0}$, both at initial year $t_0 = 1991$. This variable therefore measures the actual increase in import exposure by each US manufacturing industry s. Such a change in import exposure from China could be either due to a supply shock in its exports (e.g. producitivity growth in China's export sectors), or caused by unobserved domestic shocks in the US demand. The latter component may affect sectoral imports and sectoral employment simultaneously and therefore contaminate trade flows. To address this endogeneity concern, ADH (2013) and Acemoglu et al. (2016) suggest using the change in import exposure from China within eight other high-income countries as an instrument:

$$\Delta IP_{st}^{OTH} = \frac{\Delta M_{s,t}^{OC}}{Y_{s,t_0} + M_{s,t_0} - E_{s,t_0}}, \tag{2}$$

where $\Delta M_{s,t}^{OC}$ measures the change in *other countries imports from China* (OC) in sector s during the period t by these eight other nations,[4] which is then normalized by the initial domestic sectoral absorption in 1988 ($t_0 = 1988$). The validity of this instrument relies on the assumption that high-income countries are similarly exposed to import competition that is driven by the supply shock in China, while the industry import demand shocks are uncorrelated between these eight countries and the United States.

To capture the industrial export exposure, we start with an analogous measure to (1) as:

$$\Delta EP_{st} = \frac{\Delta X_{s,t}}{Y_{s,t_0}}, \tag{3}$$

where ΔEP_{st} measures changes in export exposure of sector s between t and t+1, defined as changes in US sector exports $\Delta X_{s,t}$, divided by the initial sectoral shipments Y_{s,t_0}. Thus,

[4]These countries are: Australia, Denmark, Finland, Germany, Japan, New Zealand, Spain, and Switzerland. An additional reason that we use these eight countries is that their disaggregated HS trade data are available since 1991.

EP_{st} is a measure of export intensity, capturing the share of export value out of the total industrial output. Different from the measure of China-specific import shock, we are interested in measuring the total US export expansion to the entire rest of the world.

To identify the effect of import and export exposure on the industrial employment, we adopt the following empirical specificaton:

$$\Delta ln(L_{st}) = \beta_t + \beta_1 \Delta IP_{st} + \beta_2 \Delta EP_{st} + \gamma X_{s0} + \epsilon_{st}, \tag{4}$$

where $\Delta ln(L_{st})$ is the annual log change in employment in sector s over time period t, X_{s0} is a set of start-of-period sectoral controls, and ΔIP_{st} and ΔEP_{st} measure the annual change in import exposure from China and the annual change in export exposure, respectively. Following Acemoglu et al. (2016), we fit this equation for stacked first differences covering two subperiods 1991-1999 and 1999-2007, where in some cases we also extend the latter subperiod to 1999-2011. All variables in changes are annualized.

As described above, equation (4) is subject to endogeneity of the trade exposure measures. As suggested by Acemoglu et al., we use an instrumental variable (IV) strategy, using the import exposure from other eight high-income economies (ΔIP_{st}^{OTH}) to instrument for the exogenous changes of import penetration from China into the United States. For export exposure, we construct two instruments. Our first instrumental variable for export exposure uses the export expansion of eight other high-income economies to the world (except the United States):

$$\Delta EP_{st}^{OTH} = \frac{\Delta X_{s,t}^{OTH}}{Y_{s,t_0}}. \tag{5}$$

Using other advanced nations' exports to instrument for the US exports closely follows the idea of ADH (2013) and helps identify the effect of both export and import changes on the US sectoral employment. It is, however, less helpful in understanding the driving forces underlying the US export growth. Indeed, Caliendo et al. (2015) show that from 1990 until 2011 both MFN tariffs and the preferential tariffs have fallen by nearly nine percent, most of which was driven by substantial trade liberalization in emerging and developing economies. Notable examples

include China's accession into the WTO in 2001, which lowered its average import tariff from above 15 percent to below 9 percent within just a few years; and the North American Free Trade Agreement (NAFTA), which integrated production chains and the flow of consumer goods across the continent of North America. Romalis (2007) find substantial increase in the trade volume and output among the United State, Canada and Mexico, particularly in the products that were previously highly protected.

Inspired by these observations, our second instrument for the US export expansion, denoted as ΔEP_{st}^{PRE}, is constructed as the predicted US exports due to reductions in import tariffs faced by the US exporters and their competitors in other countries, as described next.

2.2 Predicting US Exports

Similar to Romalis (2007), we start from a simple CES equation:[5]

$$\frac{X_{st}^{us,j}}{X_{st}^{i,j}} = \left(\frac{\tau_{st}^{us,j}}{\tau_{st}^{i,j}}\right)^{1-\sigma}, \tag{6}$$

where $X_{st}^{us,j}$ is the US exports to country j, $X_{st}^{i,j}$ is the exports from country i, $\tau_{st}^{us,j}$ and $\tau_{st}^{i,j}$ are import tariffs imposed by importer j on exports from the United States or from country i, and σ denotes the elasticity of substitution.

This equation can be re-arranged and re-written as:

$$\frac{X_{st}^{us,j}}{\left(\tau_{st}^{us,j}\right)^{1-\sigma}} = \frac{X_{st}^{i,j}}{\left(\tau_{st}^{i,j}\right)^{1-\sigma}} = \sum_{k\neq us} X_{st}^{k,j} \frac{X_{st}^{i,j}}{\sum_{k\neq us} X_{st}^{k,j}} \left(\tau_{st}^{i,j}\right)^{\sigma-1}, \tag{7}$$

where the second equation follows from multiplying importing country j's total imports across all countries but the United States, $\sum_{k\neq us} X_{st}^{k,j}$, in both the numerator and the denominator.

Summing both sides over $i \neq us$ and make a few re-arrangements, we can get:

$$X_{st}^{us,j} = \left(\tau_{st}^{us,j}\right)^{1-\sigma} \frac{\sum_{k\neq us} X_{st}^{k,j}}{(C-1)} \sum_{i\neq us} \left[\frac{X_{st}^{i,j}}{\sum_{k\neq us} X_{st}^{k,j}} \left(\tau_{st}^{i,j}\right)^{\sigma-1}\right], \tag{8}$$

[5]Derived from a CES demand system, this equation should also include the relative marginal costs between two exporting countries, which we ignore here for simplicity but will be accounted for empirically by fixed effects.

where C represents the total number of countries participating in exporting to country j. Taking logs of the above equation and ignoring the constant, we obtain:

$$\ln X_{st}^{us,j} = (1-\sigma)\ln(\tau_{st}^{us,j}) + \ln\left(\frac{\sum_{k\neq US} X_{st}^{k,j}}{C-1}\right) + (\sigma-1)\ln\left[\sum_{i\neq us}\frac{X_{st}^{ij}}{\sum_{k\neq us} X_{st}^{kj}}\left(\tau_{st}^{i,j}\right)^{\sigma-1}\right]^{\frac{1}{(\sigma-1)}}$$

Empirically, we can therefore rely on the following specification:

$$\ln X_{st}^{us,j} = \beta_0 + \beta_1 \ln(\tau_{st}^{us,j}) + \beta_2 \ln\left(\frac{\sum_{k\neq US} X_{st-1}^{k,j}}{C-1}\right) + \beta_3 \ln(T_{st}^{j}) + \epsilon_{st}^{j}. \tag{9}$$

So the US exports of good s to country j is determined by three items: first, the import tariffs imposed by j on US exporters ($\tau_{st}^{us,j}$). Second, the average total imports by j from all other exporters $\left(\frac{\sum_{k\neq US} X_{st-1}^{k,j}}{C-1}\right)$, which proxies for country j's import demand. In empirical practice, to avoid the potential simultaneity bias, we lag the import demand for 6 years. Finally the third determinant is a measure of country j's average import tariffs on all non-US imports of good s, $T_{st}^{j} = \left[\sum_{i\neq us}\frac{X_{st_0}^{ij}}{\sum_{k\neq us} X_{st_0}^{k,j}}\left(\tau_{st}^{i,j}\right)^{\sigma-1}\right]^{\frac{1}{(\sigma-1)}}$. Empirically we use the base year t_0 exports to construct weights. This term captures the substitution between US export products and their competitors: higher levels in T_{st}^{j} raises the demand for the US export. When σ approachs one, T_{st}^{j} is a geometric mean of import tariffs against all countries except the United States. While when σ approachs two, T_{st}^{j} becomes an arithmetic mean of import tariffs.[6] In the coefficients of (9), we expect to see $\beta_1 < 0$, $\beta_2 > 0$ and $\beta_3 > 0$.

2.3 Tariff and Trade Data

Equation (9) guides our estimation of US total exports using data on global trade flow and tariffs. To be more specific, we collect global trade flow data from the UN-Comtrade Database, which provides trade value by 6-digit HS and 5-digit SITC products. Tariff schedules are collected from the TRAINS and IDB databases accessed via the World Bank's WITS website, which have been complemented by mannually collected tariff schedules published by the International Customs Tariff Bureau (BITD) and made clean and available by Feenstra and Romalis

[6] We have used the geometric mean in our regressions.

(2014) and Caliendo et al. (2015). Putting these together, our empirical work is built on a comprehensive, disaagregated, annual database with trade flow and tariff schedules which are consistently matched at 5-digit SITC product classification for more than 150 countries over the period 1984 to 2011.

To facilitate the comparison with the effect of import exposure and employment changes, we construct our export exposure and the instruments for it at the revised SIC (standard industrial classification) level which was adopted by ADH (2013) and Acemoglu et al. (2016). The US export data at 6-digit HS product level could be readily converted to the revised SIC product level by adopting the crosswalk (with weights) in Acemoglu et al. (2016). We then take similar steps to contruct the export value at revised SIC level by other eight advanced economies (i.e., our first instrument for US exports, ΔEP_{st}^{OTH}).

For the second instrument, there are several steps from converting US exports at 5-digit SITC products across importing countries to measuring export exposure at the revised SIC poduct level. First, we estimate equation (9) using the above-mentioned datasets provided by Feenstra and Romalis (2014) and Caliendo et al (2016) for US exports of product g (at SITC 5-digit) across importing countries j, which are then aggregated across export destination markets to get the US industrial exports, denoted as $\hat{X}_{gt}^{SITC}$. Second, we construct a crosswalk between SITC to SIC, following Feenstra, Romalis and Schott (2002). In the cases where one SITC code is matched to multiple SIC codes, we use the initial year export value to construct weights.[7] Thirdly, we use the crosswalk provided by Acemoglu et al (2016) to convert the 1987 SIC industry code to the revised SIC code, ending up with export values for 392 revised 4-digit SIC codes, covering each year from 1991 to 2011, which we denote accordingly as $\hat{X}_{st}^{SIC} = \sum_{g \in s} \omega_{gs,t_0} \hat{X}_{gt}^{SITC}$, where s denotes the SIC sector, while ω_{gs,t_0} is the start-of-period weights used in matching SITC product g to SIC sector s.

[7]Here we adopt the 1987 SIC classification. We use US export data in 1990 to construct weights when one SITC product is matched to multiple SIC product for years between 1990 and 2000, and similarly US exports in 2000 to construct weights for years between 2000 and 2011.Details about the structure of US export data is provided in Feenstra, Romalis and Schott (2002).

The estimation results of regressing US exports at 4-digit SITC industry level on tariffs and import demand of destination markets across countries are provided in Table 1, where we experiment with various fixed effects. All regression coefficient estimates have expected signs and reasonable values, and our preferred specification, column (4), includes sector times year fixed effects. With these coefficient estimates, we then construct a measure of predicted US exports,

$$\Delta EP_{st}^{PRE} = \frac{(\hat{X}_{st}^{SIC} - \hat{X}_{st_0}^{SIC})}{Y_{s,t_0}},$$

which is at the revised SIC industry level and is used as the instrument for the actual US export expansion.

[Table 1 about here]

After the above steps, we end up with measures of the change in US import exposure from China and its instrument, as well as the change in US export exposure to the world and two instruments, for 392 revised SIC manufacturing sectors. We follow Acemoglu et al. (2016) in examining the long difference between 1991 and 1999, and between 1999 and 2007 or 2011. All trade values are measured in 2007 US dollars using the Personal Consumption Expenditure deflator.

2.4 US Employment

For US employment changes we use the County Business Patterns (CBP) for the years 1991, 1999, 2007, and 2011. We use the same data coverage as Acemoglu et al (2016) and follow their steps to merge the data into 392 manufacturing sectors and 87 non-manufacturing sectors by 722 commuting zones. For additional sectoral level information with the manufacturing sector (such as number of production workers and nonproduction workers, and a number of sectoral controls which we will discuss in detail in later sections), we use the NBER-CES Manufacturing Industry Database for the same years 1991, 1999, 2007.[8]

[8]NBER-CES database ends at year 2009.

Table 2 summarizes our main variables of interests, including the measures of import and export exposure, changes in labor employment, and instrument variables.

[Table 2 about here]

3 Exports Create Jobs in Manufacturing

3.1 Benchmark Industry Estimation

Table 3 takes a first look at the impact of US exports to the world, in addition to its import exposure from China. Following Acemoglu et al (2016), we adopt a stacked first-difference model for the two time periods 1991-1999 and 1999-2007. Column (1) starts with an OLS regression, where import exposure from China has a significant negative impact on the industrial employment growth, while export expansion creates a positive and significant effect on employment. As noted above, both estimates for the import exposure and export exposure could be biased due to simultaneous changes in domestic demand and supply. Thus in column (2) we instrument the observed changes in import and export exposure. As discussed above, for changes in import exposure, we instrument it with contemporaneous changes in import from China by other eight high-income countries. For changes in export exposure, we use two instruments to improve the estimation efficiency. The first is analogous to the import instrument, using the contemporaneous changes in export from other eight countries to the rest of world except the United States. The second instrument for export exposure is the predicted value of exports based on the specification detailed in Section 2.

After correcting the simultaneity bias, the estimates in column (2) imply that a one percentage point rise in industry import penetration reduces domestic industry employment by 1.3 precentage points, while a one percentage point rise in export expansion increases industrial employment by 0.87 percentage points. Column (3) extends the second subperiod to 1999-2011, and the results are similar qualitatively: import exposure reduces jobs while export expansion creates them. The coefficient on exports is smaller, probably reflecting the votatility in exports

during the global financial turmoil.

[Table 3 about here]

The remaining columns of Table 3 (columns (4)-(6)) look at the impact of trade exposure, but separately for different subperiods. Again, all results hold qualitatively, with negative impacts of imports and positive impact of exports. The effect of export exposure is the largest during the 1999-2007 subperiod, while the effect for import exposure is strongest during the 1991-1999 subperiod. In the bottom panels, we report the first stage regression results for the two endogenous variables, with F-statistics for the excluded instruments well above the the Stock-Yogo weak ID test critical value.

Relying on the preferred estimation results in column (2) of Table 3, we can evaluate the economic magnitude of trade shocks on labor employment. From (4), and following Acemoglu et al. (2016), changes in industrial employment brought by the increase in imports and export can be expressed as:

$$\Delta L_t = \sum_s \left(L_{s,t}(1 - e^{(\hat{\beta}_1 \Delta IP_{st} + \hat{\beta}_2 \Delta EP_{st})}) \right), \tag{10}$$

where $\hat{\beta}_1$ and $\hat{\beta}_2$ are the 2SLS coefficient estimates from (4). Hypothetically, this equation calculate the difference between the actual and counterfactual manufacturing employment in year t if there are virtually no changes in import and export exposure. Applying the actual changes in import penetration (ΔIP_{st}) and export expansion (ΔEP_{st}), we calculate the net employment changes due to trade shocks. Export expansion *net of* China import penetration actually led to a net gain of 525,000 jobs in the first period 1991-1999, while it led to a net loss of 520,000 jobs for the second period 1999-2007.[9]

[9]Two caveats are worth noting: (1) If we focus on the export channel while shut down the other (e.g. import exposure from China), then export expansion brought about 996,000 jobs in 1991-1999, and about 620,000 jobs in 1999-2007. On the other hand, if we focus on import shocks from China, the import competition led to 520,000 job losses in 1991-1999, and 1.24 million job losses in 1999-2007. (2) These quantitative predictions do not take into account the omitted variable bias due to unobserved shocks, so they may be overstating the impact of trade on manufacturing employment. Acemoglu et al. (2016) suggest using the partial R-squared from the first-stage regression to adjust the estimated coefficient of trade shocks. It becomes more complicated to do so in our case with two endogenous variables and three instruments.

Given that the observed changes in manufacturing employment over these time periods were a slight increase of 200,000 jobs in 1991-1999, and a large reduction of 3.34 million jobs in 1999-2007 (and another 2.48 million job losses from 2007 to 2011), import penetration contributed a substantial share of job losses, particularly in the second period when imports from China grew much faster. However, export expansion also created a considerable number of jobs at the same time, without which employment in US manufacturing would have been experienced a much worse contraction. On balance over the entire 1991-2007 period, therefore, job gains and losses due to changes in US global exports and Chinese imports were roughly balanced using these industry estimates.

3.2 Robustness with Additional Controls

As we have discussed above, industries subject to greater trade shocks may also be exposed to other economic fluctuations that are correlated with import and export growth. In Table 4, we add as robustness checks additional controls to address this concern. Following Acemoglu et al. (2016), we consider three groups of controls. First, column (1) includes a set of dummies for 10 one-digit broad manufacturing categories, which allows for differential trends across these one-digit sectors given our first differences specification. Column (2) considers a set of sectoral controls drawn from the NBER-CES database, including the share of production workers in sectoral employment, the log of the industrial average wage, the ratio of capital to value added (all measured in 1991), and computer and high tech equipment investment and pretrend variables in 1990 as a share of total 1990 investment. Column (3) captures the secular trend that the US manufacturing has been declining since the 1950s and the manufacturing employment has been falling since the 1980s. Such long-standing trend predates the recent rise in trade shocks and may overstate the impact of trade exposure in the current period. Thus column (3) adds the change in the industry's share of total US employment and the change in the log of the industry average wage, both measured over 1976-1991. Then in column (4), we include all three sets of controls simultaneously.

[Table 4 about here]

Throughout columns (1) to (4), the coefficient estimates for export exposure are significant and stable in magnitude. With the full sets of controls, a one percentage point rise in industry import penetration reduces domestic industry employment by 0.81 precentage points, while a one percentage point rise in export expansion increases industrial employment by 0.75 percentage points. Finally in column (5) we include a full set of dummies for the 392 four-digit manufacturing industries. Using this full set of industry dummies in the stacked first-difference specification, the effect of trade shocks is identified by *changes in* the growth rates of industry employment and the trade exposure measures in the second period (1999-2007) relative to the first period (1991-1999). The coefficient estimates in this very demanding specification are only reduced modestly. The last two columns (columns (6)-(7)) extend the coverage of the sample to 1991-2011. Column (6) uses full sets of industrial controls, with similar results, confirming the robustness of the job creating effect of export expansion. Column (7) uses the full set of industry dummies, which reduces the significance and magnitude of the estimations.

3.3 Impact on Other Industrial Outcomes

Next we explore the impact of trade exposure on other outcomes. Columns (1) to (5) of Table 5 use CBP data while columns (6)-(9) use NBER-CES database. Increasing import exposure reduces employment (col. 1), the number of establishment (col. 2), average employment per establishment (col. 3), total wage bill (col. 4); it also reduces employment of both production workers (col. 6) and non-production workers (col. 7). Interestingly, increasing import exposure increases the workers' real wage rate (col. 5), and has no significant effect on real wages of production and nonproduction workers (col. 8 and col. 9). Export expansion, on the other hand, substantially increases employment (col. 1), employment per establishment (col. 3), real wage bill (col. 4) and real wage rate (col. 5); it also increases employment in both production workers (col. 6) and non-production workers (col. 7), and the real wage of non-production workers (col. 9).

[Table 5 about here]

3.4 Accounting for Input-Output Linkages

Trade impacts may go beyond the industry boundary and propagate upstream and downstream. Note this effect is not limited within the manufacturing sector (e.g. an automobile producer may be exposured to trade shocks in upstream steel industry, or vice versa), but trade shocks in manufacturing will also affect services and other nontradable sectors. To study the interindustry linkages, we apply the BEA's input-output table for 1992.

First, the *upstream effect* of export and import exposure measures the impact of downstream sectors' trade exposure on upstream suppliers. That is:

$$\Delta IP_{st}^{up} = \sum_{g} \omega_{gs}^{u} \Delta IP_{gt}, \qquad and \qquad \Delta EP_{st}^{up} = \sum_{g} \omega_{gs}^{u} \Delta EP_{gt}, \tag{11}$$

where ω_{gs} is the use coefficient which tells the share of product s used as input in industry g, which is derived from the 1992 BEA input-output matrix. Thus ΔIP_{st}^{up} is a weighted average of the trade shocks faced by downstream buyers of products of sector s. When a downstream sector g experiences an export expansion, it may also increase its demand for intermediate inputs from its upstream sector s.

We could similarly compute the *downstream effect* of export and import exposure, which measures the impact of upstream sectors' trade exposure on downstream buyers. When a upstream sector g experiences an export expansion, it may drive up the domestic price for g, which creates negative impact on domestic downstream users in sector s. On the other hand, export expansion may improve the productivity of upstream sector g, and therefore generate postivie downstream effects on sector s.

$$\Delta IP_{st}^{down} = \sum_{g} \omega_{sg}^{d} \Delta IP_{gt}, \qquad and \qquad \Delta EP_{st}^{down} = \sum_{g} \omega_{sg}^{d} \Delta EP_{gt}, \tag{12}$$

where ω_{sg} measures the input share of product g used as input in industry s.

Using equations (11) and (12), we can generate instruments for both the upstream and downstream exposure measures. Table 6 presents the 2SLS estimation results. Column (1) focuses

on the effect of import shocks, augmented with upstream and downstream import exposure, for 392 manufacturing sectors. Besides the significant direct effect of import exposure, upstream import exposure also exerts negative impact of industrial employment, while downstream import exposure has a positive but not significant effect. Column (2) further incorporates changes in export exposure. In this case, the direct within-sector effect of export exposure is positive and significant. Furthermore, buyers' export exposure also creates significant and positive effect on the employment of upstream suppliers (as shown by the coefficient for the upstream export exposure), while the effect of downstream export exposure is not precisely estimated.

Column (3) considers only the non-manufacturing sector while columns (4) extends the sample to consider both manufacturing and non-manufacturing sectors. Although exposure at the upstream and downstream sectors exert positive effects on non-manufactuirng employment, the effects are not significant. Given that most effects come from the direct and the upstram exposure, columns (5)-(6) sum the upstream and direct trade exposures, confirming that import exposure reduces jobs while export expansion creates them.

[Table 6 about here]

Moreover, the above equations account for the direct transmission of shocks along the inter-sectoral input-output linkage. Upstream and downstream effects could also take force indirectly through iteration. For example, a shock to the plastic sector may affect downstream computer industry, and further affect transportation sector that uses a lot of computers. Such iteration of impacts across sectors generate a full chain of implied responses based on the input-output matrix. Therefore we augment the results in Table 6 with the Leontief inverse of the matrix. Results using the complete Leontief matrix are similar, and so we report them in the Appendix Table A.1.

4 Export Exposure on Local Labor Markets

The industry level results compare changes in relative employment across manufacuring sectors with different exposure to import penetration and export expansion. As emphasized by Acemoglu et al (2016), this approach cannot identify the reallocation and demand effects which occur in general equilibrium. In their influential work, ADH (2013) quantify the reallocation effects by focusing on cross-regional variations in local commuting zones' response to trade shocks. In this section, we follow ADH (2013) and Acemoglu et al. (2016) and explore the geographic differences in trade shocks, based on 722 commuting zones (CZs) that cover the entire US mainland.

We begin by first constructing the Bartik measures of CZ level import and export exposure as:

$$\Delta IP_{it}^{CZ} = \sum_{s} \frac{L_{is,t_0}}{L_{i,t_0}} \Delta IP_{st}, \qquad and \qquad \Delta EP_{it}^{CZ} = \sum_{s} \frac{L_{is,t_0}}{L_{i,t_0}} \Delta EP_{st}, \tag{13}$$

where i denotes commuting zone, s denotes SIC manufacturing sectors, ΔIP_{st} and ΔEP_{st} are sectoral import and export exposure that we have used in the previous sections. So ΔIP_{it}^{CZ} and ΔEP_{it}^{CZ} denote the increase in import and export exposure respectively, by commuting zone i for time period t (either 1990-2000, or 2000-2007). Note that L_{is,t_0} is the *start of period* employment in manufacturing sector s and commuting zone i, while L_{i,t_0} is the *start of period* total employment for commuting zone i, including both manufacturing and nonmanufacturing employment. The variation in import and export exposure across commtuing zones comes entirely from the differences in local industry structure in employment in the initial year. Figure 4 presents a comparison of the regional exposure to imports and exports during the two subperiods.

[Figure 4 about here]

As with the industry measure of trade shocks, the CZ level import and export exposure are also likely to be subject to endogneity problem. Therefore we apply the Bartik formula to

the industry level instrument ΔIP_{st}^{OTH}, obtaining commuting zone level instrument for import exposure. Directly applying the Bartik formula to the industrial *export exposure*, however, is subject to potential measurement error: the instruments ΔEP_{st}^{OTH} and ΔEP_{st}^{PRE} are intended to be *affine transformations* of actual US exports (plus an error) at the industry level, but not necessarily *equal to* such exports (plus an error). Because this transformation for each instrument can differ across industries, not correcting for it initially will lead to measurement error when aggregating to the commuting zone level. Accordingly, we correct for this potential error by regressing a panel of actual exports at SIC level on the predicted exports at the same industry aggregation, with industry fixed effects and year dummies: that is, $X_{st} = \alpha_t + \alpha_s + \delta \hat{X}_{st}^{SIC} + \nu_{st}$.[10] Then we apply to Bartik local employment weights to the fitted value of the above estimation, obtaining our two contructed commuting zone level instruments for ΔEP_{it}^{CZ}.

With both exposure measures and their instruments, we estimate the following specification across 722 commuting zones:

$$\Delta L_{it}^{m} = \beta_t + \beta_1 \Delta IP_{it}^{CZ} + \beta_2 \Delta EP_{it}^{CZ} + \gamma X_{it_0}^{CZ} + \gamma_r + e_{it}, \tag{14}$$

where ΔL_{st}^{m} is the annual change in *manufacturing employment share of the working age population* in commuting zone i over time period t. To be consistent with the industry level specification, we continue to stack the annualized first differences for the two periods, 1991-1999 and 1999-2007 (or in some specifications, 1999-2011). In all regressions, we also include β_t to control for different time trend between the two time periods, a set of census division dummies to control for regional specific trends, as well as the initial share of manufacturing workers (in 1991). All regressions are weighted by start of period (1991) commuting zone's share of national population, and the standard error is clustered at the commuting zone level.

Table 7 presents results for the manufacturing employment share. Column (1) shows that the impact of CZ level import exposure on the local manufacturing employment share is negative

[10] Running this estimation prior to the industry-level estimation won't affect these previous results in section 3 since the industry specific effects are readily controlled by the long-difference specification that we have taken, while δ does not vary across industries.

and significant. In particular, a 1 percentage point increase in average import exposure in the local commuting zone leads to a 1.66 percentage point reduction in the local manufacturing employment share. Export exposure, however, has no significant effect.

Column (2) of Table 7 further incorporates a set of commuting zone level initial demographic and economic controls, which include the percentage of college-educated population, percentage of foreign-born population, percentage of employment among women, percentage of employment in routine occupations, and finally the average offshorability index of occupations. The impact of export exposure now has a significant positive effect on local employment in manufacturing. We find that a 1 percentage point increase in average export exposure in a local commuting zone generates a 0.67 percentage point increase in the local manufacturing employment share. The magnitude for the impact of import exposure is reduced by nearly one third: a 1 percentage point increase in average import exposure now leads to a 1.32 percentage point reduction in local manufacturing employment share. Furthermore, the local manufacturing employment share at the start of period has strong negative effect on manufacturing employment share.

Quantitatively, accounting for local market effects implies increased import exposure led to a loss of about 2.73 million manufacturing jobs in local labor market from 1999 to 2007, and another 1.03 million manufacturing job losses from 1991 to 1999 . On the other hand, increased export exposure implies a gain of 1.7 million manufacturing jobs from 1991 to 1999 and 1.12 million from 1999 to 2007. In net, export exposure significantly offsets the reduction in jobs caused by import penetration but does not eliminate them, leaving about 0.9 million net job losses.

Columns (3)-(4) examine the longer period 1991-2011. The effect of export exposure on manufacturing employment is reduced slightly while that of import exposure is strengthened, probably reflecting the effect of the financial crisis.

[Table 7 about here]

We further examine the effect of trade exposure on the *non-manufacturing* share of working

age population, at the local commuting zone level. As shown in Table 8, import penetraion has no significant effect on the non-manufacturing employment, while export exposure does have a substantial and significant negative effect on non-manufacturing employment share. Recall that our export and import exposure measures are based completely on manufacturing industries. Such effects on non-manufacturing employment share may, on the one hand, reflect the reallocation of employment from non-manufacturing to manufacturing when the local area experienced an export boom. On the other hand, the effect is indirect and misses the actual direct export exposure of non-manufacturing employment through the strong exports of agriculture goods and services of the United States, as we discuss in the next section.

[Table 8 about here]

5 US Exports in Agriculture and Services

In previous sections, we present the evidence for the job creation effect of US export growth in manufacturing sectors, alongside the job destruction effect of import shock from China. The focus on manufacturing tradables, though consistent with the China shock literature, neglects important channels that the US economy may benefit from trade: first, the United States is one of the biggest exporter in agriculture products; and second, the United States runs large trade surplus in services trade. As shown in Figure 5, in the past two decades, in particular after 1999, the United States have experienced strong growth in exports in non-manufacturing goods (mainly agricultural and mining) and services. In 2011, US services exports reached above 600 billion US dollars, and US non-manufacturing goods exports reached 250 billion US dollars. Summing up, they are nearly 70% of the export value in manufacturing goods. While our main results, as other research in the literature, focus almost exclusively on the effect of trade in manufacturing goods, the strong growth in non-manufacturing goods and services certainly generates increasing demand for labor, which we plan to study in future work.

[Figure 5 about here]

6 Conclusions

First-stage F for Δ Imports	24.2								
First-stage F for Δ Exports	18.1								

Note: Robust standard errors in parentheses, clustered on three digit SIC industries. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$
The sample includes 392 SIC manufacturing sectors during two subperiods (1991-1999 and 1999-2007), the NBER-CES database excludes 8 industries due to missing data. All regressions are weighted by start-of-period employment share of the sector. First stage F-test for excluded instuments are reported in bottom. Detailed first stage results are available upon request.

Note: Robust standard errors in parentheses, clustered on commuting zones. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$
The sample includes 722 commuting zones over two stacked subperiods (1991-1999, and 1999-2007). All regressions are weighted by start-of-period population. All regressions have US census regions dummies and a time dummy for the second period. Detailed first stage results are available upon request.
