CEO Stress and Life Expectancy: The Role of Corporate Governance and Financial Distress*

Mark Borgschulte Marius Guenzel Canyao Liu Ulrike Malmendier

August 9, 2019

Abstract

Optimal pay-for-performance has to account for private benefits distorting managerial incentives. We focus on one aspect of private benefits – CEO health and mortality. Our identification exploits the staggered introduction of anti-takeover laws since the mid-1980s as well as exposure to industry shocks. Using a hand-collected data set on the dates of birth and death for more than 1,600 CEOs employed by large, publicly listed U.S. firms, we estimate that the insulation from market discipline via anti-takeover laws lowers mortality rates by six to eight percent. This effect is concentrated in the first four to five years of exposure. The estimated effect size is large compared to naturally occurring changes in life expectancy over time. We also find that CEOs who exclusively served under strict governance are more likely to pass away while in office or within the first five years of stepping down as CEO. We estimate similar effects on longevity arising from exposure to industry-wide distress during a CEO's tenure. Finally, we utilize machine-learning based age estimation software to detect visible signs of aging in CEOs who experience distress shocks. Using a difference-in-differences design, we estimate accelerated aging by roughly one year after CEOs are exposed to a distress shock.

We thank Martijn Cremers, Allen Ferrell, Kevin Murphy, and Emmanuel Saez for sharing their data. We thank Grigory Antipov, Moez Baccouche, Sid-Ahmed Berrani, and Jean-Luc Dugelay for sharing their age estimation software. We also thank seminar participants at the 2018 briq Workshop on Skills, Preferences, and Educational Inequality, University of Bonn; the 2018 Berkeley-Stanford Joint Behavioral Economics Mini-Conference; Berkeley Haas; and University of Illinois Urbana-Champaign for helpful comments and suggestions.

1 Introduction

Much of the academic and policy discussion about high-profile jobs in business and other arenas revolves around their pay, performance, and incentives. Ever since the seminal work of Jensen and Meckling (1976) on the separation of ownership and control, research focuses on the question of how to best design managerial incentives and corporate governance systems: How can shareholders minimize the moral hazard issues arising from the separation of ownership and control, and ensure that the CEO aims to maximize the value of the firm? A key ingredient in this classical agency problem are so-called "private benefits" that the CEO (but not shareholders) may obtain.

In this paper, we make the trade-off between better incentives to maximize shareholder value and private benefits concrete for one aspect of private benefits – CEOs' health and longevity. We document substantial effects on mortality rates arising from variation in the stringency of corporate governance or the experience of industry-wide distress shocks.

In a typical incentive-design problem, private benefits b are often an unspecified proxy for perks a manager might be extracting from the firm. The discussion of private benefits in the previous literature often revolves around these perks the CEO is able to extract – from the $6,000 gold-and-burgundy shower curtains of Tyco's former CEO Dennis Kozlowski to multi-million dollar self-dealings via low-interest loans, transfer pricing, or greenmail payments with mixed motives. Less attention has been paid to the potential personal cost, especially health costs, that arise from assuming a top leadership position and being exposed to monitoring and criticism during times of crisis. While the news media may occasionally cover unexpected deaths "in office" and discuss the stress associated with C-suite positions, there is little research done to assess and quantify these costs. CEOs work the long hours and have demanding schedules (Bandiera et al. 2017; Porter and Nohria 2018). What are the implications of heightened supervision and pressure for the CEO's health, ability to stay on the job, and ultimately willingness to select into the CEO position?

In this paper, we provide an assessment of the health costs associated with serving as CEO

under harsher business conditions. Building on the literature in labor and health economics that has established a link between job stress and health outcomes for lower-income employees (e.g., Cheng et al. 2005; Hummels et al. 2016), we show a significant impact of more stringent monitoring on the health of top-level managers, a demographic group with high income, socioeconomic status, and prestige. We show that CEOs who become insulated from hostile takeovers and resulting job loss through anti-takeover laws have six to eight percent lower death rates. Similarly, mortality risk increases by four to six percent after CEOs experience a period of industry-wide distress, providing further evidence that hostile job environments can result in significant personal costs for CEOs. Our results indicate that stricter corporate governance regimes – which are generally viewed as desirable and welfare-improving – imply significant personal health costs.

To quantify the adverse effects of the stress and pressure that come with the position of the CEO on life expectancy, we hand-collect birth and death data of more than 1,600 former CEOs of large U.S. firms. The sample of CEOs we use as a starting point for these searches comes from Kevin Murphy (cf. Gibbons and Murphy 1992) and contains CEOs of large U.S. firms included in Executive Compensation Surveys published in *Forbes* who were in office between 1970 to 1991. Combining multiple information sources including historical newspapers, company websites, and Ancestry.com, we are able to find the exact birth and death information for 87% of CEOs of our initial sample.

We first exploit variation in the intensity of CEO monitoring due to the staggered passage of anti-takeover laws in different U.S. states since the mid-1980s to examine the effect of variation in monitoring on CEOs' health outcomes. These laws, passed by the majority of U.S. states (66%), shielded CEOs from market discipline by making hostile takeovers by corporate raiders more difficult. Previous research has shown that CEOs were less tough in wage negotiations with employees and labor unions, and shied away from both plant creation and closures after enactment of these laws (Bertrand and Mullainathan 2003). Hence, the introduction of anti-takeover laws arguably made life easier for CEOs, and led to personal benefits that included lower job-related stress.

In our main specifications, we focus on the introduction of Business Combination (BC) laws, as they are generally recognized as most effective among the anti-takeover laws introduced since 1982, and have been at the core of prior research that exploits the passage of anti-takeover laws as identifying variation. Our results are robust to using the first-time enactment of any of the five most commonly introduced types of anti-takeover laws since the mid-1980s, to taking into account other state- or firm-level anti-takeover provisions and to excluding lobbying and opt-out firms (Karpoff and Wittry 2018), and to different data cuts based on firms' industry affiliation or state of incorporation. Furthermore, to alleviate selection concerns, we restrict all our analyses to CEOs who were appointed before the enactment of the laws we study.

To describe the relationship between CEOs' exposure to lenient corporate government laws and their lifespan, we fit hazard regression models. All specifications control for age, cohort, and firms' industry and location. To investigate the effects of working conditions distinct from changes in tenure as CEO, we present estimates without and without controls for the CEO's tenure. Adding tenure controls isolates the effect of working conditions, but can introduce bias from "bad controls" (Angrist and Pischke 2008). We show that in our setting any bias is likely small and would attenuate our results.

We find that anti-takeover laws led to significant improvements in the life expectancy of incumbent CEOs. Non-parametric plots show a visible divergence in longevity comparing CEOs with and without exposure to anti-takeover laws, and suggest that the effect of reduced monitoring on lifespan is nonlinear. The first four to five years of exposure to lenient governance are associated with increasing gains to life expectancy; our hazard models estimates imply that one additional year under lenient corporate governance lowers mortality rates by six to eight percent. Additional years of exposure have no incremental effect on longevity.

The estimated effect sizes are large by comparison to general health trends. For example, at age 60, the one-year mortality rate of a male American born in 1925 is 1.733%. The one-year exposure effect of approximately seven percent pushes this rate down to 1.612%, in between those

for 60-year-olds born in 1928 and 1929.[1] Our estimates imply that a typical range of prolonged exposure to lenient governance leads to life expectancy gains of up to one and a half years.[2] While these effects are sizable, they are substantially lower than the health costs associated with health threats such as smoking, which is estimated to reduce the life expectancy of smokers by ten years and more compared to non-smokers (HHS 2014; Jha et al. 2013).

We also zoom in on the first five years after a CEO resigns to shed light on the short-to-medium-term impact of variation in exposure to market discipline and governance on longevity. Consistent with the long-term effects, the fraction of CEOs who pass away within the first five years after stepping down is higher for CEOs who exclusively served under strict governance. 5.6 percent of CEOs who began their tenure in the 1980s and eventually became protected by a business combination law pass away within five years of stepping down, compared to 7.8 percent of CEOs from the same cohorts who exclusively experienced the strict governance regime.

Next, we provide complementary evidence on the effect of stressful periods on a CEO's health exploiting industry-level distress shocks as a measure of an exogenous increase in a CEO's stress levels. We find that the experience of an industry-wide downturn – a separate and directionally opposite change in stress levels compared to BC law passage – increases a CEO's mortality risk by a very similar magnitude, approximately four to six percent.

In the final part of the paper, we document more immediate health implications of experiencing financial distress on CEOs' health. We utilize machine-learning algorithms designed to estimate a person's "apparent" age, to detect visible signs of aging in the faces of CEOs. Specifically, we obtain access to the software of Antipov, Baccouche, Berrani, and Dugelay (2016) that was

[1] At age 60, the one-year mortality rate of a male American born in 1928 is 1.640%, and that of a male American born in 1929 is 1.599%. We use 1925 as the baseline birth year as this is the median birth year of CEOs in our sample. Mortality probabilities are taken from the *Life Tables for the United States Social Security Area 1900-2100* and are available here.

[2] Life expectancies are also taken from the *Life Tables for the United States Social Security Area 1900-2100* and are available here. We discuss the calculation of life expectancy gains in more detail in Section 3.3. In addition, we acknowledge and, in fact, document ourselves in Section 3.1 that CEOs live significantly longer than the average population, on which the *Life Tables* are based. Therefore, we emphasize the interpretation in terms of *differences* in life expectancies rather than levels.

trained on more than 250,000 pictures and is the winner of the *ChaLearn Looking At People 2016* competition in the *Apparent Age Estimation* track.[3] We collect a sample of 3,113 pictures of CEOs from the 2006 *Fortune 500* list at different points during their tenure to estimate how fast they age and, in particular, how the experience of industry shocks affects the speed of aging. We base our sample collection on the 2006 *Fortune* list to ensure sufficient variation in the exposure to industry shocks across CEOs as induced by the financial crisis. Using a difference-in-difference regression design, we estimate that CEOs look about one year older in post-crisis years if their industry experienced a severe decline in 2007-2008. We account for endogenous selection out of the CEO job through an instrumental variables approach based on 2006 CEO status (intention-to-treat analysis). We also document that accelerated aging as a result of experiencing industry shocks during the crisis is not a temporary phenomenon. Instead, we see a slight *increase* in aging differences between distressed and non-distressed CEOs over time, reaching about 1.3 years for pictures taken five years and more after the onset of the crisis.

Our results imply significant personal costs in form of detrimental health effects arising from increased monitoring and industry distress. Heightened stress from serving under stricter governance and during economic downturns appears to constitute a substantial personal cost for CEOs in terms of their health and life expectancy. An interesting open question is whether managers are fully accounting for these costs as they are progressing on their career paths, and what the implications for selection are.

Related Literature. Our paper adds to several strands of literature. First, it connects to a recent literature that sheds light on CEOs' demanding job and time requirements. Bandiera et al. (2017) obtain weekly diaries of 1,114 CEOs of manufacturing firms, with detailed information on CEOs' activities. The average CEO's weekly schedule was comprised of 202 15-minute time blocks,

[3]In the field of Computer Science, winning important programming contests is, loosely speaking, comparable to being accepted at a top-five Economics or top-three Finance journal. The software we use was the winner of the second edition of the competition. While we have no information on how many teams participated in 2016, more than 100 teams participated in the first edition, and our software improved on the solution of the first edition's winner.

adding up an average of 50 work hours. 30% of CEOs worked a six-day or seven-day week. The schedule appears to be even more intense in large firms. Porter and Nohria (2018) track 27 CEOs of multi-billion dollar firms 24/7 over three months,[4] and record CEOs working an average of 62.5 hours per week, 79% of weekend days, and 70% of vacation days. It is easy to complement the literature with anecdotal evidence. In 2015, Oscar Munoz, CEO of United Airlines, Inc., suffered from a heart attack at age 56, just a few weeks after assuming the role of CEO, reportedly having been "extremely stressed in the days and weeks leading up to [the attack]."[5] Turning to examples from CEOs included in our sample, Leo D. Goulet, former CEO of the Gerber Products Company, died from a heart attack at age 61, two months after taking over the CEO position.[6] Frank P. Nykiel, former CEO of Chromalloy, opted for an early retirement, citing poor health as the reason.[7] Our paper is the first comprehensive assessment of the health costs associated with the CEO position.

Second, we contribute to the literature at the intersection of finance and health economics that studies the impact of the stock market on people's physical and psychological health. Engelberg and Parsons (2016) link shocks to firm performance (stock market crashes) to investors' health conditions. They report a strong and nearly instantaneous relationship between stock market crashes and hospital admissions, especially strong for anxiety-related reasons and panic disorders. Our paper builds on these findings by showing that periods of economic and financial distress have adverse health consequences for managers as well, and in addition, establishes a novel link between work-related stress and a CEO's health outcomes stemming from "good," i.e. stringent, corporate governance.

Third, our paper links to the health and labor literature on worker job stress and insecurity and resulting health effects. Cheng et al. (2005) report a strong positive association between job

[4]The average annual revenue of their firms is $13.1 billion. For comparison, the average firm in Bandiera, Hansen, Prat, and Sadun (2017) has annual sales of $222 million.

[6] The New York Times, 07/07/1987, "Leo D. Goulet, Leader Of Gerber Foods, Dies."

[7] The New York Times, 06/30/1982, "Sun Chemical Chief Heads Chromalloy." Nykiel passed away on 11/18/1994 at the age of 76. During his time as CEO at Chromalloy, he fought an attempted takeover by The Sun Chemical Corporation.

insecurity and poor health (mental health, vitality, and general health). Browning et al. (2006), instead, do not find any links between job loss and immediate health effects in terms of hospitalization. Caroli and Godard (2016) find evidence that job insecurity affects specific types of health outcomes, such as headaches or eyestrain. Kuka (2018) reports that higher generosity of unemployment insurance leads to better self-reported health. Hummels et al. (2016) show that when workers' job demands increase due to plausibly exogenous reasons (foreign demand shocks), they suffer from more stress, injury, and illness. The authors estimate increases in depression rates of 2.5% and in hospitalizations due to heart attacks of 15%. Our paper extends this literature by documenting adverse health effects of high job demands for CEOs, a group for which job loss will not imply financial constraints, and by focusing on corporate governance which is generally viewed as desirable from a shareholder and welfare perspective. To the best of our knowledge, the only other work that has looked at executives' lifespans is Yen and Benham (1986), distinguishing between CEOs in more and less competitive industries. However, their analysis is based on a much smaller sample of executives, does not take into account self-selection into certain job environments, and instead of a rigorous survival analysis merely provides a simple comparison of means of CEOs' age at death across industries.

Fourth, our paper is related to the literature that studies how socioeconomic status affects people's health and their life expectancy. Cutler et al. (2006) write that "[o]utside of economics, the currently dominant theory of health differentials is that the poor health of low status individuals is caused by 'psychosocial stress'—the wear and tear that comes from subordinate status and from having little control over one's own life." The economics literature has oftentimes also studied the health benefits associated with high socioeconomic status. Rablen and Oswald (2008) compare the longevity of Nobel Prize winners and those who were merely nominated; their estimates suggest that winners outlive "losers" by one to two years. Similarly, Fleisher et al. (2017) analyze academicians in China and find that being elected to the Chinese Academy of Sciences or Engineering prolongs their lifespan by 1.2 years on average. Borgschulte and Vogler (2017) find that

the winners of close elections outlive losing candidates. By focusing on CEOs, our study extends this stream of literature and takes it to the corporate setting. In particular, we also quantify the flipside of high socioeconomic status in the case of the CEO's position, arising from heightened stress and demanding work schedules.

Finally, in terms of identification and application, we add to the literature in corporate governance on the impact of business combination laws, and anti-takeover laws more generally. This literature has generally found that anti-takeover laws have weakened corporate governance and as a result, increased managerial slack. Bertrand and Mullainathan (2003) were the first to use the staggered introduction of BC laws as plausibly exogenous variation in corporate governance. They find that after their introduction, wages rose, and both creation and destruction of new plants fell, suggesting that managers "enjoy a quiet life" when possible. Giroud and Mueller (2010) show that the effect of BC laws on managerial slack is concentrated among firms in non-competitive industries, consistent with the notion that competition maintains managerial effort. Gormley and Matsa (2016) show that after the adoption of BC laws, managers even undertake explicit, value-destroying actions that reduce their firms' risk of distress, to make their job easier and safer. Atanassov (2013) reports that anti-takeover laws also impacted innovative activities. Specifically, he shows that patent count and quality decreased with the introduction of anti-takeover laws. Cheng et al. (2004) find that managers reduce their stock ownership following the enactment of BC laws, consistent with managers viewing both stockholdings and BC laws as (substitute) channels through which managers increase the control of the firm. Cain et al. (2017) study the relation between anti-takeover laws and hostile takeovers. They find that fair price laws predict less hostile activity, but also that "business combination laws [...] have no discernible impact on hostile activity." Karpoff and Wittry (2018) formulate similar concerns regarding the reliance on BC laws without taking into account the institutional and legal context of the laws. We address these points in three ways. First, in Section 3.4.2, we show that our results are robust to jointly examining the five most common second-generation anti-takeover laws, by using the first-time enactment of any of those

to identify changes in corporate governance stringency. Second, in Section 3.4.3, we implement the additional tests suggested in Karpoff and Wittry (2018), excluding from the analysis firms that lobbied for the second-generation anti-takeover laws, opted out of coverage by the laws, or had firm-level takeover defenses in place, and focusing on the time period after the first-generation laws were struck down by courts. We also show that our results are robust to various data splits based on firms' state of incorporation or industry affiliation. Third, in Section 4, we find similar adverse effects of harsh work environments on a CEO's lifespan when departing from concentrating on anti-takeover laws and focusing on exposure to industry distress instead. Our paper differs from the above literature on anti-takeover laws in that we explore the *personal-level* consequences of changes in corporate governance. Many of the mechanisms and channels suggested by the above papers work through the specific incentives to the CEO, but we are the first to look into the long-term health consequences of such incentivization. In a broader sense, we show that corporate governance mechanisms do not only impact firm-level outcomes, but also influence the personal domain of relevant actors, with CEOs and C-suite managers being a leading candidate. We conclude that higher incentives can enhance productivity and shareholders value, but might come with a dark side and adverse effects on managers' health.

The remainder of the paper is organized as follows. Section 2 describes our data and methodology. Section 3 contains our results pertaining to life expectancy and exposure to anti-takeover laws. Section 4 presents the results pertaining to life expectancy and exposure to industry-wide distress shocks. Section 5 presents our preliminary evidence on CEOs' aging patterns. Section 6 concludes.

2 Data and Methodology

2.1 Anti-Takeover Laws

Anti-takeover statutes are passed by states to increase the hurdles for hostile takeovers. The second-generation[8] anti-takeover laws were comprised of several types of statutes. Besides Business Combination laws, states also frequently passed Control Share Acquisition and Fair Price laws, as well as Poison Pill and Directors' Duties laws, since the mid-1980s. We refer to Section 3.4.2 for a discussion of the latter types of laws, and focus here on BC laws.

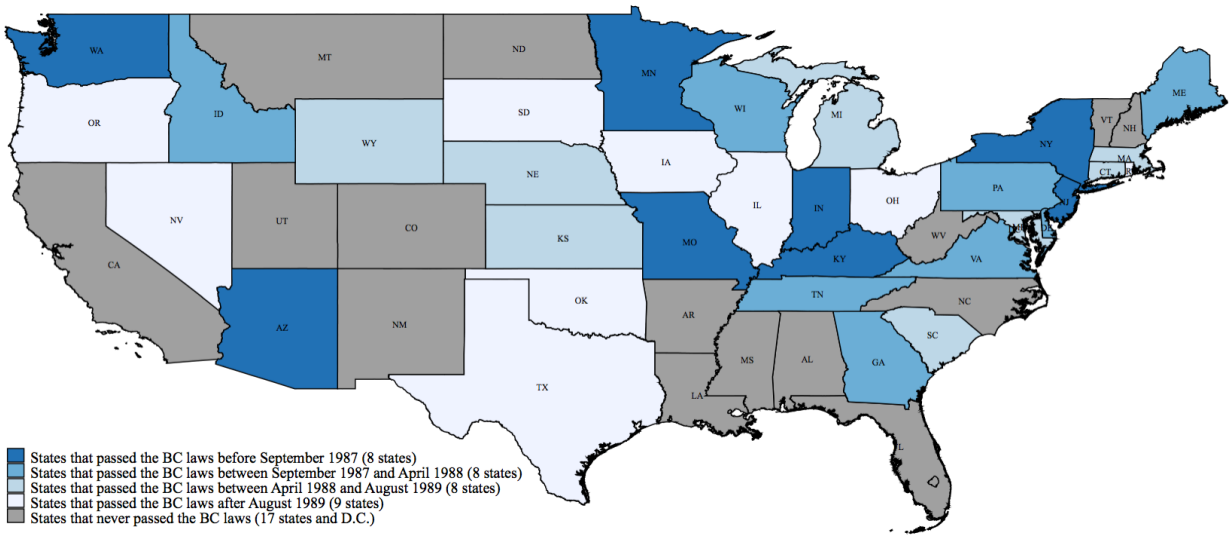

BC laws contributed to reducing the threat of hostile takeovers by imposing a moratorium that prohibits a large shareholder of a firm from conducting certain transactions with the firm, usually for a period of three to five years. Figure 1 visualizes the staggered introduction of BC laws across states. A total of 33 states passed a BC law between 1985 and 1997, with most laws being passed between 1987 and 1989. (Appendix-Figure B1 contains a similar map based on all five types of second-generation anti-takeover laws listed above.)

The fact that there is both variation across time and states in terms of the introduction of the BC laws is obviously very useful for identification, and one reason for the popularity of these laws in academic studies. Another advantage of using the passage of anti-takeover laws as identifying variation in corporate governance is that these laws applied to firms based on the state in which they were incorporated and not where they were headquartered or operated. The frequent discrepancy between firms' location and their state of incorporation enables us to assess the impact of the laws while concurrently controlling for shocks to the local economy.

[8]These laws are referred to as second-generation anti-takeover laws, since they were passed after the first-generation laws were struck down by courts. See also the discussion in Cheng, Nagar, and Rajan (2004) and Cain, McKeon, and Solomon (2017).

Figure 1: Introduction of Business Combination Laws Over Time

This figure visualizes the distribution of Business Combination law enactments over time. In total, thirty-three states passed a BC law between 1985 and 1997. The map omits the state of Hawaii, which never passed a BC law.

2.2 CEO Sample

The original sample of CEOs comes from Kevin Murphy's data on CEO compensation.[9] The data covers the years 1969 to 1991, and is an extended version based on Gibbons and Murphy (1992). They follow all CEOs listed in Executive Compensation Surveys published in *Forbes* during the sample years. These surveys are derived from corporate proxy statements and include the executives serving in the largest U.S. firms. The data set comprises more than 3,400 CEOs from over 1,600 firms. 102 CEOs serve as the CEO for multiple firms in the data set. Correcting for this and restricting to CEOs who are included in the data set in 1975 or later and whose firm can be assigned a PERMNO from CRSP reduces our sample to 2,720 unique CEOs from 1,501 firms.

For these CEOs, we manually search for (i) their exact dates of birth to verify the birth year

[9]The data was collected by Kevin Murphy and was provided to us by Emmanuel Saez. For a detailed overview on data construction rules and procedures, we refer to Gibbons and Murphy (1992).

information provided in the original data set, (ii) whether the CEO has died or is still alive, and (iii) the date of death, if the CEO has passed away. The cutoff day for (ii) is October 1st, 2017; that is, all CEOs who did not pass away by this date are treated as alive in all of our analyses, even if they have died since then. To obtain the information on birth and death, we use Google searches as well as Ancestry.com. Ancestry.com has comprehensive information on people's historical birth and death records, combining information from U.S. Census, Social Security Death Index, birth certificates, and other historical sources. Ancestry.com allows us to find the precise birth and death information even if we cannot find such information through newspaper searches, as long as we can be certain that we have uniquely identified the correct person on Ancestry.com. To do so, we would compare the Ancestry's information with that from Google searches and information in newspapers, such as birth place, elementary school, or city of residence. Identifying a person as alive turns out to be more difficult than identifying someone as dead. Even if we cannot locate the person on Ancestry.com, large newspapers such as the New York Times or Los Angeles Times will oftentimes report about the death of a famous former CEO; however, there tends to be less coverage of retired CEOs who are still alive. We classify a CEO as alive whenever we are able to find recent sources confirming their alive status. Most often, these sources are either newspaper articles or websites listing the CEO as a board member, sponsor, donor, or chairman/chairwoman of/for an organization or event.[10] We are able to obtain the birth and death information for 2,361 out of the 2,720 CEOs from above, implying a finding rate of 87%, employed by 1,352 different firms.[11]

In addition to these CEO-level variables, we collect information on historical states of incorporation. One major advantage of using anti-takeover laws as exogenous variation to corporate governance is that they apply to firms independently of their state of location, headquarters, and main business activities. We start from the information provided in CRSP/Compustat, but cannot

[10]For sources that include a date, we only use sources from 01/2010 or after to conclude the person is still alive.

[11]To be conservative and reduce noise, in cases in which we are not sure about whether the CEO is still alive or has passed away, we drop the CEO from our sample.

simply use this information for the past since CRSP backfills the state of incorporation with the current one. In a first step, we compare the state of incorporation currently listed in CRSP to that listed in the SDC Mergers and Acquisitions and SDC New Issues databases. Whenever they deviate, we manually search for which information is correct and whether (and when) firms switched their state of incorporation. [12] We start from the current information provided in CRSP/Compustat and from Compustat Snapshot, firms' 10-Ks and other filings with the Securities and Exchange Commission, legal documents and newspaper articles. In total, we are able to identify the (historical) state of incorporation for 2,199 out of the 2,361 CEOs that remain in our main sample after the CEO birth and death information search phase.

In a final step, we return to CEO-related variables and collect two more pieces of information. First, we collect the actual tenure of all CEOs in the firms in which they appear in our data set.[13] Whenever possible we use Execucomp to fill in this information, and otherwise revert to Google searches. In this case, the New York Times *Business People* section proves especially useful, as it frequently reports about executive changes in our sample firms. We retain CEOs only if we can find at least yearly information on when they started and ended their tenure. When included in Execucomp or when we can find announcements of CEO changes in newspapers, we are oftentimes able to obtain the exact date or month of the CEO transition.[14] Second, we restrict our sample to

[12] Prior literature has dealt in different ways with firms' deliberate choice to change their state of incorporation. For example, Bertrand and Mullainathan (2003) do not correct for state of incorporation changes in their main specification. They randomly check 200 firms in their sample and find that only three had changed their state of incorporation in the past. In robustness tests, they restrict to non-Delaware firms. Giroud and Mueller (2010) proceed accordingly. Cheng, Nagar, and Rajan (2004) report that none of their 587 *Forbes 500* firms changed their state of incorporation between 1984 and 1991. Gormley and Matsa (2016), instead, include historical information from SEC disclosure compact discs, Compustat back-tapes, SEC Analytics, as collected by Cohen (2012), and the legacy version of Compustat. In addition, they drop firms that changed their state of incorporation from treated to non-treated states or vice versa. Cain, McKeon, and Solomon (2017) rely on SEC Analytics, SDC and Compustat as well, and in addition on historical Moody's manuals.

[13] As explained above, our starting sample only contains years in which a firm appeared in the *Forbes* Executive Compensation Surveys. Oftentimes, there are gaps over time, or firms are only included in few years, which complicates the tenure classification. In addition, whenever we do not observe a predecessor or successor CEO in our data already, we cannot simply assume that the first (last) year in which we observe the CEO is also their first (last) year of tenure, and need to search for this information ourselves.

[14] Whenever we have yearly information only, we assume the CEO change happened in the middle of the year ("mid-year convention"). This is motivated by the notion that starting months of CEOs included in Execucomp are

CEOs whose firm was included in CRSP during the time of their tenure.[15] After these restrictions, we end up with a sample of 1,900 CEOs. To alleviate selection concerns, we present all results focusing on CEOs who were appointed in years prior to the enactment of the business combination laws, leaving us with a main sample of 1,605 CEOs.[16]

2.3 Variable Construction

Appendix A contains a description of all variables used in this study. Our first set of variables pertains to the birth and death information of the CEOs in our sample. *YearOfBirth* is the year of birth of a CEO. *DeadOct2017* is a dummy variable that equals 1 if a CEO has passed away by the censoring date, October 1st, 2017, and 0 otherwise. *DateOfDeath* is the death date of a CEO. *YearOfDeath* captures the year of death of CEOs, is, however, calculated up to the monthly level. That is, *YearOfDeath* would be 2000.5 for a person who died in June 2000. Besides year of birth, alive status and date of death (when applicable), we define several additional variables capturing various aspects of a CEO's tenure. *Tenure* captures a CEO's tenure, *BC* his exposure to a BC law, and *FL* his exposure to the firstly enacted second-generation anti-takeover law.

CEO-Year Level Structure and Intra-Year Data. We construct our data set in CEO-year level format. As a result, $Tenure_{i,t}$ is defined as a running variable, counting a CEO's cumulative tenure from appointment until year t. Similarly, $BC_{i,t}$ and $FL_{i,t}$ capture the cumulative exposure to BC and FL laws. For example, $BC_{i,t}$ would take the value 3 if the CEO has experienced three years under the BC regime until year t (including t). In addition, since we measure these three variables capturing a CEO's cumulative experience in years, we want to emphasize that they can

relatively uniformly distributed throughout the year (see Eisfeldt and Kuhnen (2013)).

[15] Note that this constraint is different from above where we required that we be able to assign a PERMNO to each firm in our sample. For instance, we would drop a person in this final step if he served as the CEO before the firm went public.

[16] We proceed accordingly for the analyses regarding the first-time enactment of any of the five second-generation anti-takeover laws; i.e., we require that the CEO is appointed before the first law is passed. This yields a sample of 1,510 CEOs. As an aside, throughout the paper, we use the pronoun "he" when referring to the CEOs in our sample since the vast majority of observations in our sample are male CEOs.

take non-integer values. For example, Delaware's BC law was adopted on 2/2/1988. A CEO's BC exposure in 1988 would then be calculated as $BC_{i,1988} = \frac{365-\text{doy}(2/2/1988)}{365} = 0.92$. Similarly, CEOs not starting their tenure or stepping down at the beginning or end of the year can result in non-integer values for cumulative tenure. Finally, we also calculate squared cumulative tenure, $Tenure^2_{i,t}$, as well as a CEO's age in year t ($Age_{i,t}$).

2.4 Empirical Strategy

We use a hazard model to analyze the effect of anti-takeover laws on the health outcomes of CEOs Designed for survival analyses, the hazard model is an intuitive choice in our setting. A CEO enters the hazard model (i.e. "becomes at risk") in the year he is appointed CEO and exits the model when he dies or on October 1st, 2017 (censoring date). We refer to this period as the CEO's spell. To obtain a CEO-year level panel and accommodate time-varying covariates, we reshape the spell data into one-year-long sub-spells.[17] Hence, each sub-spell (but the first and final one) captures one calendar year. The main goal of the hazard model is to analyze how survival—in a literal sense—varies with the passage of a BC law, associated with reductions in the fear of hostile takeover as well as stress job- and career-related stress. We start with the following baseline model:

$$\Pr(Death_{i,t}) = \beta BC_{i,t} + \gamma_1 Tenure_{i,t} + \gamma_2 Tenure^2_{i,t} + \boldsymbol{\delta}' \boldsymbol{X}_{i,t} + \varepsilon_{i,t} \tag{1}$$

$BC_{i,t}$, $Tenure_{i,t}$, and $Tenure^2_{i,t}$ are as defined in the previous subsection. As discussed there, these variables capture a CEO's cumulative tenure and exposure to BC laws over time, given that our data is in CEO-year format. $\boldsymbol{X}_{i,t}$ is a vector of control variables controlling for year, birth year, age, industry, and industry. $Death_{i,t}$ takes the value 1 in the sub-spell in which the CEO dies and

[17] The first and final sub-spells for each person are shorter than one year. The first sub-spell captures the time (in years) between a CEO's start date and the end of the same year, and consequently, is shorter than one year unless the CEO started his tenure in January. The final sub-spell is, for CEOs who have passed away, the fraction of the calendar year they survived (e.g., 0.5 for a person who died on June 30th), and for CEOs still alive, 0.75 (= 9/12, given the censoring date of October 1st, 2017).

exits the hazard model, and takes the value 0 otherwise.

Nonlinearity in Effect of Lenient Governance on Life Expectancy. While we begin our analysis with the baseline model of Equation 1, non-parametric Kaplan-Meier survival plots of the data (see Section 3.2 for details) reveal that the effect of insulation from takeover threat on a CEO's long-term health and mortality is nonlinear; initially, there is a positive response of long-term health to lowered monitoring and takeover threats, but the *incremental* benefits from prolonged exposure to reduced monitoring and stress taper off eventually. This is consistent with the notion that CEOs with high BC exposure have inevitably *self-selected* into a long tenure. For these CEOs, prolonged reductions in monitoring might have minimal effects on long-term health, as their self-selection reflects that they are in good health anyway.[18]

To account for the possibility of nonlinear effects, we will focus our discussion on a modified version of Equation 1 that separates the effects of initial and later years of exposure to lenient governance on survival rates:

$$\Pr(Death_{i,t}) = \beta_1 BC_{i,t}^{(\min\text{-}p50)} + \beta_2 BC_{i,t}^{(p51\text{-}\max)} + \gamma_1 Tenure_{i,t} + \gamma_2 Tenure_{i,t}^2 + \boldsymbol{\delta'} \boldsymbol{X}_{i,t} + \varepsilon_{i,t} \quad (2)$$

We maintain the CEO-year level structure discussed above, so that $BC_{i,t}^{(\min\text{-}p50)}$ and $BC_{i,t}^{(p51\text{-}\max)}$ capture cumulative exposure over time. $BC_{i,t}^{(\min\text{-}p50)}$ captures below-median exposure to a business combination law, while $BC_{i,t}^{(p51\text{-}\max)}$ captures above-median exposure. The median CEO who experienced a BC regime was exposed to it for 4.4 years; thus, we choose 4.4 as the cutoff point. We define the variables such that $BC_{i,t}^{(\min\text{-}p50)}$ captures initial exposure, and that $BC_{i,t}^{(p51\text{-}\max)}$ picks up the incremental effect (larger than 4.4-year exposure) on health outcomes.[19]

[18] Apppendix-Figure C1 shows that irrespective of whether they were exposed to BC laws or not, CEOs with longer tenure have a higher probability of being alive in 2017, accounting for year of birth, CEO appointment age, industry, and location, consistent with the notion that long tenure anticipates a longer life.

[19] For example, for a CEO with a current BC exposure of four years, $BC_{i,t}^{(\min\text{-}p50)}$ would take the value 4, and $BC_{i,t}^{(p51\text{-}\max)}$ the value 0. In the following year $(t+1)$, assuming the CEO stays in office, $BC_{i,t+1}^{(\min\text{-}p50)}$ would be set to 4.4, and $BC_{i,t+1}^{(p51\text{-}\max)}$ to 0.6. In year $(t+2)$, $BC_{i,t+2}^{(\min\text{-}p50)}$ remains at 4.4, and $BC_{i,t+2}^{(p51\text{-}\max)}$ increases to 1.6.

Tenure Controls. We estimate Equations 1 and 2 using the Cox (1972) proportional hazard model. We report results with and without controls for tenure. The primary motivation for adding controls for tenure is that the business combination laws are associated with significant gains in tenure,[20] and we would like to isolate the effect of working conditions, i.e. stress experienced as CEO, from the effects of additional years served. The inclusion of an endogenous control comes at the price of introducing selection bias into the estimates (Angrist and Pischke (2008)). We provide a longer discussion of this issue in Appendix Section C.[21] We conclude from this discussion that the bias likely attenuates our results. Empirically, the controls have little effect on our results.

3 Results: Corporate Governance and Life Expectancy

3.1 Summary Statistics

Table 1 presents the summary statistics for our main sample covering 1,605 CEOs, as well as sub-samples split by BC exposure.[22] Panel A on the upper left shows the statistics for the pooled sample of 1,605 CEOs. The median CEO in our sample was born in 1925, became CEO at age 52, and served for nine years. There is relatively large heterogeneity in tenure; moving from the 10th to the 90th percentile adds 17 years of tenure. 71% of our CEOs have passed away by October 1st, 2017. The median CEO died at age 83, and passed away in 2006.

Panel B at the bottom presents the summary statistics separately for CEOs with no BC exposure ($N = 980$), those with positive but below-median exposure ($N = 320$), and those with higher levels of exposure ($N = 305$). While some of the differences in variables across sub-groups are already

[20] Appendix-Table B1 estimates a hazard model in which the outcome is CEO departure. The estimated hazard ratios on BC exposure are around 0.9 and significant, confirming that BC laws reduce the likelihood that the CEO steps down in a given year.

[21] See also the discussion on endogenous controls in the context of anti-takeover laws in Gormley and Matsa (2016).

[22] We collapse variables that are defined in a cumulative way (i.e., in CEO-years), such as tenure and BC exposure, to the CEO-level. That is, we calculate a CEO's total tenure, total BC exposure etc. and base our summary statistics on these values.

Table 1: Summary Statistics

This table presents summary statistics for our main sample covering 1,605 CEOs. We collapse variables that are defined in a cumulative way (i.e., in CEO-years), such as tenure and BC exposure, to the CEO-level. That is, we calculate a CEO's total tenure, total BC exposure etc. and base our summary statistics on these values. *DeadByOct2017* is a dummy variable that equals 1 if the CEO has passed away before the censoring date and zero otherwise. *AgeTak.Office* and *YearTak.Office* refer to the CEO's age and the year at appointment, respectively.

suggestive of the effects we have in mind—e.g., 82% of CEOs without BC exposure have passed away, but only 68% (38%) of CEOs with below-median (higher) BC exposure—we need to be careful to not over-interpret them. In particular, BC laws were only introduced starting in 1985; consequently, CEOs who served towards the beginning of our sample are less often insulated from the laws during their tenure. This is, for example, reflected in the differences in starting years as CEOs. The median CEO without BC exposure began his tenure in 1974. In comparison, the median CEO with some (high) BC exposure is appointed in 1980 (1982). In turn, these differences in start years contribute, at least partially, to the stark discrepancies in death rates across groups until the censoring date. Another cross-group comparison that has to be done carefully is that of age at death. A simple comparison between groups would overlook the fact that CEOs with BC exposure are, on average, born later. As a result, conditional on having passed away until 2017, we would expect their age of death be lower compared to their No-BC peers. We believe the main takeaway from this cross-group comparison ought to be that it underscores the importance of controlling for covariates such as age and cohort. It also motivates our controls for tenure, as we observe a right shift in the tenure distribution moving from zero to positive BC exposure.

Panel C on the upper right presents information on the most frequent Fama and French (1997) 49 industries in our sample, as well as most common states of incorporation. Across CEO sub-groups split by BC exposure, our CEOs are frequently employed by firms in the banking, utilities, and retail industry. Further common industries are petroleum and natural gas, as well as transportation for CEOs with no BC exposure and insurance for CEOs with BC exposure. While differences in industry frequencies are small across group, we include industry fixed effects in all analyses. In addition, we show that the results are robust to excluding specific industries, in particular "Banking" and "Utilities." Consistent with the prior literature, the most common state of incorporation is Delaware in all sub-groups. Other common states include New York, Ohio, New Jersey, and Pennsylvania.

3.2 Graphical Evidence

Before turning to the results of the hazard models, we provide graphical evidence supporting our conjecture that CEOs who served under stricter corporate governance regimes, i.e. harsher conditions, die earlier than their peers who were insulated from hostile takeovers by a BC law.

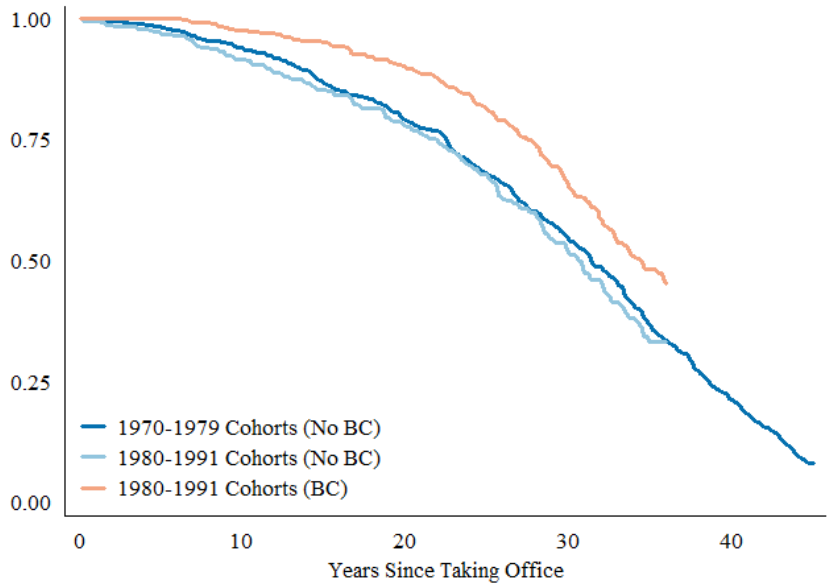

Figure 2 plots the Kaplan-Meier survival graphs separately for CEOs who served in high-stress and low-stress environments, respectively. The Kaplan-Meier estimator is a non-parametric estimator of the discrete hazard. Discretizing time into intervals $t_1, ..., t_J$, it is defined as $\widehat{\lambda_j^{KM}} = \frac{f_j}{r_j}$, where f_j is the number of spells ending at time t_j and r_j is the number of spells that are at risk at the beginning of time t_j. In both panels of Figure 2, the vertical axis shows the fraction of CEOs who are still alive (percent survival). The horizontal axis reflects time elapsed (in years) since a person became CEO.

Panel 2a compares the survival of CEOs who became CEO in the 1970s and left office before 1980, those who became CEO in the 1980s and never served under a BC law, and those who became CEO in the 1980s and were eventually insulated by a BC law during their tenure. For the "1970s cohorts," maximal elapsed time since our sample start is $t = 47.75$ (time elapsed between 1/1/1970 and the censoring date, 10/1/2017). Similarly, for the "1980s cohorts," maximal elapsed time is $t = 37.75$. We restrict the graph to periods when at least 30 CEOs in either cohort group are uncensored, explaining the slightly earlier ends of the survival lines (after 36 and 45 years, respectively). The survival functions provide first evidence that serving under more stringent corporate governance is associated with adverse consequences in terms of life expectancy. Two results emerge. First, the survival patterns of the "1970s cohorts" and the "1980s cohorts without BC exposure" are remarkably similar, allaying concerns that our results might pick up *general* changes in survival patterns between the 1970s and 1980s. Second, consistent with our hypothesis, the survival line for the "1980s cohorts with BC exposure" is visibly right-shifted compared to the No-BC-cohorts. Most importantly, survival rates are substantially more favorable even when hold-

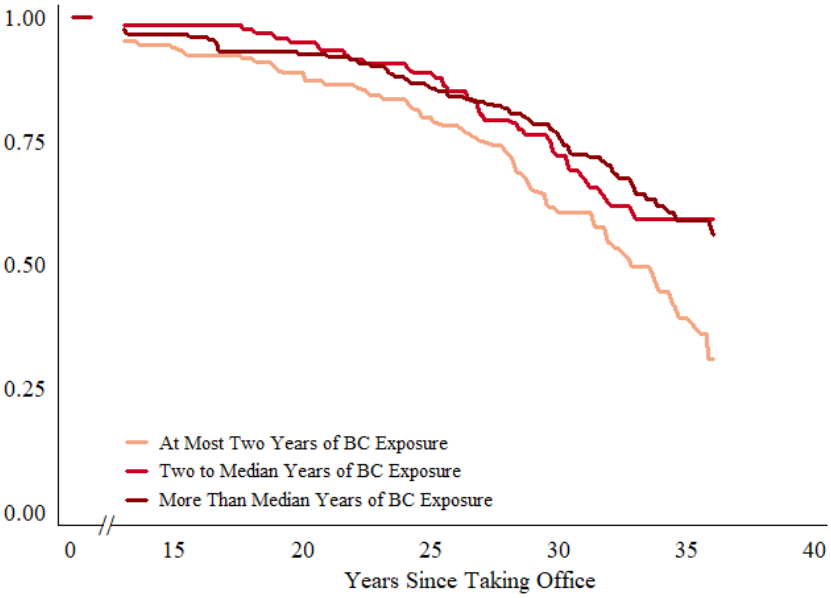

Figure 2: Kaplan-Meier Survival Estimates

This figure shows Kaplan-Meier survival plots. The vertical axis shows the fraction of CEOs who are still alive (percent survival). The horizontal axis reflects time elapsed (in years) since a person became CEO. Panel 2a compares the survival of CEOs who became CEO in the 1970s and left office before 1980 (light blue), those who became CEO in the 1980s and never served under a BC law (dark blue), and those who became CEO in the 1980s and were eventually insulated by a BC law during their tenure (orange). Panel 2b zooms in on this last group with BC exposure, and plots survival separately for CEOs with positive but at most two years of BC exposure (orange), with two to median exposure (red), and with above-median exposure (brown). Survival estimates in panel 2b are adjusted to a tenure of 12 years (median tenure of CEOs with BC exposure).

(a) By Cohort

(b) By Years Under BC Law

ing the cohort fixed, i.e. by comparing the "1980s cohorts" with and without BC exposure. For example, 20 years after a CEO's appointment, about 25 percent of CEOs from the "1980s cohorts without BC exposure" have died, whereas it takes closer to 30 years until a quarter of the CEOs in the "1980s cohorts with BC exposure" have passed away.

Panel 2b zooms in on the CEO group with BC exposure and explores potential nonlinearities in the insulating effect of more lenient governance on lifespan. Specifically, we plot survival rates separately for three sub-groups, formed as (i) positive but at most two years of BC exposure, (ii) more than two years of but at most the median BC exposure (4.4 years), and (iii) more than the median BC exposure.[23] The survival patterns *do* point to important nonlinearities in the data. Comparing CEOs with low (up to 2 years of) BC exposure to those with more exposure, we observe increased benefits in survival rates for the latter groups, visible by the rightward shifted survival lines for CEOs with more exposure. However, there is no *further* rightward shift comparing CEOs with medium and high BC exposure; instead, the survival curves of those two groups closely follow each other. This indicates that there are increasing health benefits from leniency in monitoring initially, but that the *incremental* effect of more BC exposure tapers off eventually. In light of these observed patterns, we will focus our discussion in the following sections on the modified hazard model of Equation 2 that allows us to separately capture the effect of initial and prolonged exposure to lenient governance on longevity.

3.3 Hazard Model Results

Tables 2a and 2b present the results of the Cox (1972) proportional hazard models (Equations 1 and 2), with and without controls for tenure, respectively. In both tables, Column (1) estimates our

[23]The estimated survival functions in panel 2b are adjusted to a tenure of 12 years, which is the median tenure of CEOs with BC exposure. Since we are holding fixed the cohort ("1980s cohort with BC exposure") across sub-groups, which in turn are formed based on differential exposure to BC laws, we would otherwise run the risk of comparing CEOs with substantially different lengths of tenure, potentially conflating the independent effect of tenure with the direct effects of corporate governance on working conditions.

baseline model, in which we do not separate into initial and subsequent effects of BC laws, but simply include one variable capturing cumulative exposure over time ($BC_{i,t}$). Columns (2) to (5) then use the modified hazard model, splitting cumulative exposure into below-median ($BC_{i,t}^{(\min\text{-}p50)}$) and above-median ($BC_{i,t}^{(p51\text{-}\max)}$), to account for potential nonlinear effects on health of additional years under a more lenient governance regime. All regressions control for age and location fixed effects[24] (in addition to cumulative tenure and squared tenure in Table 2a). In both tables, Columns (1) to (3) linearly control for time, Columns (3) to (5) add controls for industry fixed effects (using the Fama and French (1997) classification of firms into 49 industries), Column (4) controls for year fixed effects, and Column (5) includes birth year fixed effects. All coefficients are shown as hazard ratios, so a coefficient smaller than 1 means that the risk of failure (death) decreases with positive values of that variable. We cluster standard errors at the state of incorporation level, given that the BC laws were introduced based on firms' state of incorporation (i.e., treatment status is determined based on a firm's state of incorporation). As pointed out in Section 2.2, we restrict our analysis to CEOs who were appointed before the enactment of a BC law to alleviate selection concerns.

In the baseline regression of Column (1), we estimate a hazard ratio that is below 1 on BC exposure; it is significant when we exclude tenure controls (hazard ratio of 0.955; p-value of < 0.01), but is insignificant when we include tenure controls (hazard ratio of 0.988; p-value of > 0.10). In light of the discussion in Section 2.4 and the survival function split for differential exposure to BC laws shown in Figure 2, pointing to diminishing incremental beneficial effects of being exposed to the law, these somewhat inconclusive results might not be unsurprising. Moving to the modified model in Column (2), we estimate a strong effect of initial BC exposure on long-term survival rates independent of whether we add tenure controls or not. The hazard ratios on below-median exposure in Column (2) are 0.935 and 0.907 in Tables 2a and 2b and are significant at one percent. The hazard ratios on above-median BC exposure instead, are close to one and clearly insignificant,

[24]We follow Gormley and Matsa (2016) in assigning location based on headquarters instead of state of incorporation, since most firms' main operations are in the state where its headquarters is located. In robustness checks, we verify that our main results remain unaffected when we instead include state of incorporation fixed effects.

Table 2a: Hazard Model

This table presents the results of the Cox (1972) proportional hazard model (Equations 1 and 2). Fixed effects are included as indicated at the bottom of the table. Standard errors, clustered at the state of incorporation level, are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively. All variables are defined in Appendix A.

control variables, confirm the visual evidence from the Kaplan-Meier plots of Figure 2 that CEOs who served under more lenient corporate governance live longer, and that the effect is concentrated in initial years of exposure.

In terms of economic magnitudes, the average hazard ratio across Tables 2a and 2b implies a reduction of about seven percent in the relative death rate stemming from initial exposure to lenient governance. Applying this change to the one-year mortality rate of a 60-year-old male American born in 1925, we estimate a shift from 1.733% to 1.612% resulting from one additional year of lenient monitoring; the latter rate is in between the death probabilities of 60-year-olds born in 1928

and 1929. In turn, at age 60, American males born in 1925 have a remaining life expectancy of 17.73 years, compared to 17.95 (18.25) years for those born in 1928 (1929). Hence, our estimates translate into a birth year effect of several years, as well as meaningful shifts of remaining life expectancy.[26] Applying the median BC exposure effect to these estimates—above-median exposure is insignificantly related to longevity in the hazard models—, our estimates yield that prolonged exposure to lenient governance can lead to life expectancy gains of up to one and a half years.[27] While our estimated effects are sizable, they are, as discussed above, many times smaller than the health costs associated with known health threats; smoking, for example, is associated with reduced lifespans by ten years and more (HHS (2014), Jha et al. (2013)).

One potential concern with using cumulative exposure to BC laws as the explanatory variable of interest is that less-healthy CEOs serve for shorter amounts of time, and hence have lower exposure to BC laws. We address this in several ways. First, our graphical evidence in Figure 2b directly accounts for differences in tenure. Second, we present regression models that include controls for cumulative tenure, and hence, compare the survival of CEOs at similar tenure levels. Turning to the coefficients on the control variables in the hazard model, we indeed see that tenure, particularly long tenure, predicts lifespan. This is consistent with the notion that healthy CEOs self-select into long tenure. Finally, the results are insensitive to tenure controls, suggesting that any correlation between years of service under the BC laws and ex ante life expectancy has minimal effect on our main estimates of the effects of the BC laws.

Unsurprisingly, the coefficient on *Age* is significantly positive (i.e. the hazard ratio is above one), meaning older people are more likely to die. In the specifications in which we control for time linearly (Columns (1) through (3)), the hazard ratio coefficient on *Year* is mostly insignificant.

In summary, the hazard estimation results lend strong support to the hypothesis that changes in

[26] As noted above, our CEOs have a longer average life expectancy compared to the *Life Tables* data, which are based on the general population. Hence, we emphasize the interpretation in terms of *differences* rather than levels.

[27] A 4.4-year BC effect yields a reduction in the one-year mortality rate of 25%; $\exp(4 \times \ln(0.93)) = 0.75$. This translated into birth cohort differences of fifteen years, and the *Life Tables* indicate that American males born in 1940 have a remaining life expectancy of 19.34 years, roughly 1.5 years longer than those born in 1925.

stress levels experienced as a CEO, e.g. in the form of reduced stress arising from a more lenient corporate governance regime, have significant effects on a CEO's long-term health.

3.4 Robustness Tests

We conduct three additional checks and extensions that corroborate our findings from Section 3.3. In the first robustness test (Section 3.4.1), we re-estimate the hazard models presented in the previous section but include additional controls for CEO and firm characteristics. The second and third robustness test take into account other anti-takeover laws and considers legal and institutional context of the laws. Specifically, in Section 3.4.2, we estimate our hazard models using the first passage of any of the five most common second-generation anti-takeover laws as the year that governs the switch from high-stress to low-stress work environment. This approach follows Cheng, Nagar, and Rajan (2004) and the robustness check in Atanassov (2013). In Section 3.4.3, we implement the tests suggested in Karpoff and Wittry (2018); we exclude firms that lobbied for the anti-takeover laws, opted ouf of coverage by the laws, or had firm-level defenses in place, and show robustness to various data cuts based on industry affiliation, state of incorporation, and when first-generation laws were invalidated.

3.4.1 Additional CEO and Firm Controls

In this robustness test, we augment the hazard models shown in Table 2a, i.e. the model with tenure controls, with additional CEO and firm controls. Specifically, we include a CEO's total compensation as well as proxies for firm size (total assets and total number of employees) as additional regressors. Information on executive compensation is included in the data provided by Kevin Murphy (Gibbons and Murphy (1992)). Data on firm assets and employees is from CRSP Compustat.[28]

[28]For all three additional regressors, we linearly interpolate missing data points. Nonetheless, the number of observations decreases, as there are observations where data on one of the three additional controls is missing in all

Appendix-Table B2 contains the results when controlling for CEO pay and firm size. Two findings emerge. First, the coefficients on BC law exposure are almost identical to those in Table 2a. As in Table 2a, the estimated hazard ratio on below-median BC exposure ranges between 0.935 and 0.950, and if anything, statistical significane becomes stronger; in Column (5), the coefficient on below-median BC exposure is now significant at five percent. Second, in none of the five models, any of the coefficients on the additional control variables is significant. This might reflect endogenous selection on observables; managing larger firms might be more stressful (and come with more compensation), but only CEOs more stamina might opt for these jobs. In terms of pay, the results are also in line with the notion that in very upper tail of the income distribution, income is no longer correlated with health outcomes (Chetty et al. (2016)).

3.4.2 First-Time Enactment of Second-Generation Anti-Takeover Laws

Our analyses thus far have focused on the adoption of BC laws as the main source of identifying variation. As a second robustness test, we turn to other types of anti-takeover laws. In addition to BC laws, there are four other types of laws that were passed by individual states since the 1980s: Control Share Acquisition laws, Fair Price laws, Directors' Duties laws, and Poison Pill laws. Control Share Acquisition laws raised the bar for a hostile acquirer to gain control of a firm, since they prohibit anyone acquiring a large equity stake to use their voting rights. Fair Price laws also increased the hurdles and cost of a hostile takeover, since they dictate that acquirers pay a fair price for shares acquired in a takeover attempt, where fair could, e.g., mean the highest price paid by the acquirer for shares of the target within the last 24 months (cf. Cheng, Nagar, and Rajan (2004)). Directors' Duties laws extended the board members' duties to incorporate the interests of non-investor stakeholders, providing legal justifications to make decisions that do not necessarily maximize shareholder value. Poison Pill laws guaranteed that the firms covered by the law had the right to use poison pill takeover defense, and thus further protected these firms from takeovers.

years.

We concentrated on BC laws above as they have been shown to create substantial conflicts of interest between managers and shareholders and unveil managerial preferences (Bertrand and Mullainathan (2003), Gormley and Matsa (2016)). Our goal is not to take a stance on whether BC laws constituted the most important legal variation in the 1980s impacting the effectiveness of corporate governance (see Cain, McKeon, and Solomon (2017) and Karpoff and Wittry (2018)). To show the robustness of our results, we re-estimate our hazard models in Equations 1 and 2, using the first-time enactment of any of the five anti-takeover laws discussed above as identifying variation. We refer to the first of the five laws passed by a given state as the *First Law*. Appendix-Figure B1 visualizes the *First Law* enactment by states over time.

Appendix-Tables B3a and B3b present the results of this robustness test based on exposure to any second-generation law, again with and without tenure controls.[29] The order of inclusion of control variables and fixed effects is identical to that in Tables 2a and 2b. Consistent with our findings from above, we estimate a significant increase in longevity for CEOs who served under a less stringent governance regime, again concentrated within the initial years of exposure. Without splits into low and high law exposure, the hazard ratio on *First Law* exposure is below 1 but is, as before, only significant with no tenure controls. The hazard ratios on below-median cumulative exposure robustly yield economically and statistically strong effects; coefficients range from 0.918 in Columns (2) and (3) of Table B3b to 0.952 in Column (4) of Table B3a, significant at five percent in Columns (4) and (5) of Table B3a, and one percent in the all remaining specifications. The hazard ratios imply an effect size that is similar compared to our main specification using BC laws; averaging across columns in Tables B3a and B3b yields reductions in mortality rates by six to seven percent with the first-time introduction of any type of anti-takeover law.

Following the robustness checks for BC laws in Section 3.4.1, we also re-estimate *First Law* hazard models with tenure when including the additional CEO and firm level controls from above (pay, assets, and employees). The results are presented in Appendix-Table B4 and give the same

[29] We now split into below-median and above-median FL exposure; the cutoff is 4.45 (before 4.41 years).

patterns; the coefficients on below-median exposure to anti-takeover are nearly unaffected by the additional controls.

The additional tests based on all second-generation anti-takeover laws provide further robustness to our results. Moreover, they highlight that our results should not be interpreted narrowly in the sense of applying to BC laws specifically, but instead more broadly as applying to various types of laws and regulations that affected job-related stress of CEOs more generally.

3.4.3 Institutional and Legal Context of the Anti-Takeover Laws

In a recently published paper, Karpoff and Wittry (2018) emphasize that the institutional and legal context of anti-takeover laws should be taken into consideration when using these laws for identification in corporate finance settings. They propose an array of robustness tests, revolving around firms that lobbied for or opted out of the laws or adopted firm-level defenses, and around robustness to first-generation laws. We implement these tests in this section.[30]

In a first robustness check, we re-estimate our hazard models excluding 46 firms which Karpoff and Wittry (2018) identify as having lobbied for the passage of the second-generation anti-takeover laws. For these lobbying firms, the passage of laws does not serve as an exogenous shock, but is, instead, endogenous. Panel A of Appendix-Table B5 shows that the estimated coefficients when excluding lobbying firms are close to the previous estimates both in terms of magnitudes and significance. The hazard ratios on below-median BC exposure range between 0.926 and 0.939 and are significant at five percent or better.

In a second check, we remove firms that opted out of coverage by the second-generation laws from the analysis. Following Karpoff and Wittry (2018), we use data from the Institutional Shareholder Services (ISS) Governance (formerly, the RiskMetrics) database, covering 1990 to 2017, to identify opt-out firms. The ISS database includes dummy variables for all five anti-takeover laws

[30] For brevity, we report results with tenure controls only.

indicating whether firms had opted of coverage by that law in a given year.[31] As shown in Panel B of Appendix-Table B5, the results are nearly unaffected when dropping opt-out firms.

In a third check, we take into account whether firms adopted firm-level anti-takeover defenses in addition to coverage by state-wide provisions. As Karpoff and Wittry (2018) argue, changes in corporate governance induced by the passage of state-wide laws may not be as strong for firms with firm-level defenses in place as for firms without such defenses. Following Karpoff and Wittry (2018), we combine data from two sources to identify firms with firm-level defenses. The first data source is again the ISS database, covering the years since 1990. In addition to the variables related to anti-takeover laws, the database contains information on whether a firm adopted any firm-level provisions in a given year, such as golden parachute, cumulative voting, or confidential voting. The second data source is data provided to us by Cremers and Ferrell (2014), who extend the G-index measure of corporate governance (Gompers, Ishii, and Metrick (2003)) for the time period from 1977 to 1989.[32] Pancel C of Appendix-Table B5 shows the results when excluding all firm-years where firm-level defenses were in place; as above, the hazard ratio coefficient estimates are only marginally affected.

Beyond advocating for these (largely) cross-sectional tests, Karpoff and Wittry (2018) are also concerned about the potential confounding effects of first-generation anti-takeover laws. They argue that since the first-generation anti-takeover laws truly lost their effect only starting from June 1982 after the *Edgar v. MITE* ruling, firms in the control (i.e. no BC exposure) group before 1982 might also experience lenient governance because of the coverage by first-generation laws. We address this concern through three cuts of the data. First, we restrict our sample to years from 1982 onwards only. Second, we restrict to CEOs who stepped down in or after 1982, and as a result, served during the "post-first-law period." Third, we restrict to the CEOs who began their tenure in or after 1982. Appendix-Table B6 shows the results for all three sub-sample tests. As expected in

[31] We identify 30 firms from our sample that opted out of one or more anti-takeover laws in at least one year.

[32] We back out whether firms used firm-level defenses during 1977-1989 by "subtracting" the state-wide laws in place from the G-index, which combines firm-level and state-level defenses.

light of the cuts of the data, we lose some statistical power as we restrict to fewer CEOs, reflected in larger standard errors (especially so in Columns (5) and (6)). That said, the hazard ratio points estimates on below-median exposure are relatively stable across specifications and data cuts, and if anything, are further from 1 compared to the main results presented in Table 2a. Taken the three year-based data cuts together, we conclude that our findings robust to accounting for the timeline of the first-generation laws.

As a final robustness check, we move beyond the tests suggested in Karpoff and Wittry (2018) and create sub-samples based on firms' state of incorporation and industry affiliation (see Giroud and Mueller (2010) and Gormley and Matsa (2016) for similar robustness checks). Specifically, in Panel A of Appendix-Table B7, we exclude firms that are incorporated in Delaware or in New York (the two most common states of incorporation in our sample, see Table 1). In Panel B and C of Appendix-Table B7, we drop from the sample firms that are classified as "Banking" or "Utilities" firms based on the Fama-French 49 industry classification. Across panels and regression columns, the hazard ratio estimates on below-median BC exposure are barely affected by these various data cuts. We note that as before, our regressions sometimes lack statistical power due to the large reductions in sample size (especially so if we drop Delaware and New York firms, which excludes more than 50% of our sample). In summary, these results corroborate our main findings and show that they are not affected by firms in somewhat "special" industries, by firms incorporated in "popular" states, or by certain events in these states that happened concurrent with the introduction of anti-takeover laws.

3.5 Short-Term Effects of Stress on Health

We also analyze the short-term effects of stress on CEO mortality, by comparing the fraction of CEOs who passed away within the first five years after leaving office across different sub-groups. To do so, we again group CEOs into cohorts based on their overall exposure to a BC law. Following

the sorting in Figure 2a, we look at CEOs who enter and exit our data set in the 1970s, those who enter in the 1980s and never serve under a BC law, and those who enter in the 1980s and do eventually serve under lenient governance.

Figure 3 indicates a clear gap in the cumulative fraction of deaths between the latter two groups, while the difference between the first two groups is smaller and undetermined towards the beginning. The "1980s cohorts with BC exposure" have consistently lower rates of deaths within the first five years after stepping down compared to earlier cohorts, and most importantly, compared to CEOs from the same cohorts but who never had any BC exposure. For example, five years after leaving office, the fraction of CEOs in the "1980s cohorts without BC exposure" who have passed away is 7.8 percent, whereas that of CEOs in the "1980s cohorts with BC exposure" is only 5.6 percent—a decrease of 2.2 percentage points, or 28%.

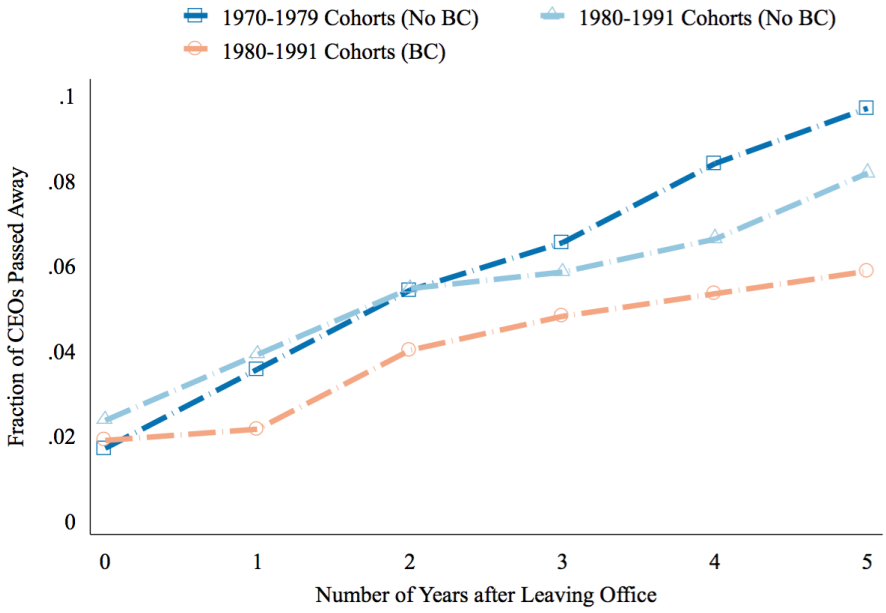

In summary, this analysis adds an additional layer of results—not only is more stringent corporate governance associated with higher mortality rates of CEOs in the long run, it also appears to be linked to higher probability of death soon after a CEO steps down.

3.6 Corporate Governance Stringency and CEO Pay

If more stringent corporate governance translates into poorer health outcomes in terms of reduced life expectancy, will CEOs who are exposed to harsher conditions bargain for higher compensation? From a theoretical perspective, the hypothesis of a positive relationship between job demands and pay follows from contract theory and compensating wage differentials. However, models of agency conflicts and managerial entrenchment predict higher pay once CEOs are insulated from the risk of a hostile takeover, allowing them to skim more resources. Bertrand and Mullainathan (2001) discuss the motivating theories based on contracting and skimming models and find empirical support for the latter in the context of anti-takeover laws. They estimate a statistically significant *increase* in total pay of approximately 5% for CEOs protected by BC laws.

Figure 3: Fraction of CEOs that Passed Away after Leaving Office

The figure shows the cumulative fraction of CEOs that passed away within the first five years after leaving office for different cohorts. The length of time between stepping down and passing away is calculated using month-level data. If the time length is t years and m months with $m < 6$, it will be classified as t years. If $m \geq 6$ instead, it will be classified as $t + 1$ years. For example, 0 years means that the CEO died in office or within the first six months after stepping down. The figure compares the share of deaths of CEOs who enter and exit our data set in the 1970s and thus never experienced a BC law, those who entered in the 1980s and never served under a BC law, and those who entered in the 1980s and did eventually serve under a BC law.

Our data allows us to revisit the findings in Bertrand and Mullainathan (2001). As mentioned above, the intital data set from Kevin Murphy (Gibbons and Murphy (1992)) contains yearly information on a CEO's pay. The pay data is available for 63% of CEO-years until 1991.[33] In Table 3, we regress CEOs' total compensation (in logs) on exposure to BC laws and an set of control variables following Bertrand and Mullainathan (2001). Columns (1) and (2) include cumulative BC exposure as the main regressor in line with our previous hazard models. Columns (3) and (4)

[33]The data set in Gibbons and Murphy (1992) ends in 1991; therefore, we do not have data on CEO pay after 1991. Since no states passed BC laws before 1985, we include total BC exposure in the regressions in Table 3, as a split into below and above the median exposure (4.4 years in our sample taking into account years after 1991) is not meaningful given the sample used for Table 3 ends in 1991.

include dummy variables for BC exposure instead, in line with Bertrand and Mullainathan (2001). Across columns, we observe a positive coefficient on the BC coefficient. The magnitudes are close to those estimated in Bertrand and Mullainathan (2001). While our results lack the same level of statistical significance compared to those in Bertrand and Mullainathan (2001)—none of the BC coefficients in Table 3 are significantly different from zero—we can reject the *one-sided* null hypothesis that the coefficient is smaller or equal to zero at conventional levels in all four regressions (the p-values vary between 0.054 and 0.100). The loadings on control variables are sensible and consistent with those in Bertrand and Mullainathan (2001); for example, we estimate a strong, positive associated between CEO compensation firms size as measured by assets and number of employees.

In summary, our results are consistent with the evidence in Bertrand and Mullainathan (2001) and suggest that CEOs became more entrenched and skimmed more resources from the firm when they were less disciplined by corporate governance. In other words, the results provide support *against* the idea that CEOs who worked during periods of higher scrutiny and increased takeover threats bargained for a compensating wage differential.

4 Results: Financial Distress and Life Expectancy

We now turn to a different shock to a CEO's stress level: industry-wide distress shocks. Distress shocks constitute a useful alternative approach to analyzing the health consequences of a CEO's job. They induce a shift in stress levels in opposite direction compared to that of insulating anti-takeover laws, and are of less permanent nature; yet, they plausibly lead to a substantial temporary increase in stress factors. Like anti-takeover laws, industry distress has been frequently used to analyze firm-worker-related questions, but not much is known about the potential health consequences for the parties affected.[34]

[34]For example, Opler and Titman (1994) study the interaction of industry distress and high leverage. Acharya, Bharath, and Srinivasan (2007) analyze the effect of industry distress on defaulted firms and creditor recoveries.

Table 3: Business Combination Laws and CEO Pay

This table presents regressions in which a CEO's total compensation is regressed on BC exposure and a set of control variables following Bertrand and Mullainathan (2001). Fixed effects are included as indicated at the bottom of the table. Standard errors, clustered at the state of incorporation level, are shown in brackets. p-values for a *one-sided* test H_0: $\beta_k \leq 0$, H_A: $\beta_k > 0$, where k refers to the coefficient on *BC* or *BC Dummy*, are shown in parentheses. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively. All variables are defined in Appendix A.

In the spirit of Opler and Titman (1994) and Acharya, Bharath, and Srinivasan (2007), we define an industry as distressed in year t if the median firm's two-year stock return (forward-looking) is less than -30%. We follow Babina (2016) for the details of this definition. In particular, we (i) use SIC3 industry classes for this analysis, (ii) restrict to single-segment firm from CRSP/Com-

Babina (2016) explores the impact of distress of worker exit rates and entrepreneurship.

pustat, i.e. disregard firms with multiple reported segments in the Compustat Business Segment Database, (iii) drop single-segments firms if the reported segment sales differ from those in Compustat by more than 5%, (iv) restrict to firms with sales of at least $20 million, and (v) exclude industry-years with fewer than four firms.

Applying this approach to identifying industry distress to our CEO panel, we find that 648 out of the 1,605 CEO, or 40%, experience at least one industry shock during their tenure. However, industry shocks are rare. Conditional on witnessing distress, the median CEO experiences one year of distress, the 75th percentile CEO two years, and no CEO experiences more than 9.7 years of distress.[35] We then relate cumulative distress experience to a CEO's life expectancy. Given that CEOs only infrequently suffer from them, with the large majority experiencing no more than two years of distress, we do not separately analyze the incremental effects of high exposure (which would be estimated off of very few CEOs) As before, we show our estimates with and without controls for tenure.[36] In addition, all models control for exposure to BC laws, given our evidence that these laws significantly contribute to a CEO's lifespan.

Tables 4a and 4b present the results with and without tenure controls, respectively. Similar to above, all regressions control for age and location fixed effects (in addition to cumulative tenure and squared tenure in Table 4a). In addition, all regressions control for BC exposure, and in both Tables, Columns (1) and (2) linearly control for time, Columns (2) to (4) add controls for Fama-French 49 industry fixed effects, Column (3) includes year fixed effects, and Column (4) birth year fixed effects.

Across specifications and independent of whether we control for tenure or not, the hazard ratios on *Industry Distress* reveal substantial adverse effects of industry shocks on CEOs' long-term health. The hazard ratios range from 1.042 in Columns (1) and (3) of Table 4b to 1.070 in Column

[35] Again, we allow for non-integer values of distress experienced, if a person is appointed as CEO or steps down during the year, and we classify that industry-year as distressed.

[36] We do this even though we find no evidence that distress significantly impacts a CEO's departure probability from the CEO position. In all but one hazard specifications presented in Appendix-Table B8, industry distress is insignificantly linked to the probability of leaving the CEO position.

Table 4a: Hazard Model (Industry Distress)

This table presents the results of the Cox (1972) proportional hazard model, using industry distress as a measure of high-stress periods for CEOs. Fixed effects are included as indicated at the bottom of the table. Coefficients are reported as hazard ratios. Standard errors are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively. All variables are defined in Appendix A.

(4) of Table 4a, and are significant at conventional levels in all regressions. These estimates point to similar effect magnitudes as before. For example, a five percent increase in mortality rates of a 60-year-old born in 1925 increases his one-year mortality likelihood from 1.733% to 1.820%. The latter probability is between the mortality rates of 60-year-olds born in 1920 and 1921, again implying multi-year effect when expressed in terms of birth year differences. Similar to above,

Table 4b: Hazard Model (Industry Distress, Without Tenure Controls)

This table re-estimates the hazard models presented in Table 4a without controls for CEO tenure. Fixed effects are included as indicated at the bottom of the table. Coefficients are reported as hazard ratios. Standard errors are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively. All variables are defined in Appendix A.

these differences correspond to plausible impacts on life expectancy; at age 60, the difference in remaining life expectancy between American men born in 1925 and 1920 (1921) is 0.42 (0.2) years.

The estimated coefficients on the control variables are similar to above. As before, in the specifications with tenure, we see that long tenure is linked to a longer life. Also as before, the coefficients on *Age* are positive (hazard ratio above one); older people are more likely to die. The hazard ratios on *Year*, in the linear time controls specifications, are again very close to one. We also point out that the coefficients on BC exposure are largely unaffected by the addition of industry

distress to the model. Below-median BC exposure is estimated to result in meaningful reductions in mortality rates in all eight specifications of Tables 4a and 4b, significant at five or one percent.

In the Appendix, we show further robustness to the financial distress results. First, we again augment the models with tenure controls with additional CEO and firm-level controls for pay, assets and employees. These results are included in Appendix-Table B9. Second, we show robustness to estimating the models based on an extended sample of CEOs, including the 295 CEOs we dropped from the analysis thus far as they were appointed after the introduction of BC laws. These results are included in Appendix-Tables B10a (with tenure controls) and B10b (without tenure controls). The estimated coefficients for both robustness tests are very close to those in the main text and corroborate the effect sizes discussed above.

All together, the industry shock analysis lends strong support to the notion that significant and unexpected changes in the work environment of CEOs have meaningful effects on their health in terms of life expectancy.

5 Results: Aging

In this final section of the paper, we move beyond the focus on longevity and ask instead whether there are more immediate, non-death manifestations on CEOs' health associated with heightened stress and demanding job environments. We ask whether stress and, in particular, experience of industry distress translates into accelerated aging of CEOs. For this analysis, we make use of the very recent advances in machine learning related to *apparent* age estimation. Thus far, most age estimation softwares have focused on estimation of a person's *biological*, i.e. "true" age. Only recently, there has been a boost in research aimed at estimating a person's apparent age, i.e. how old a person looks. The progress on this area has been made possible by the development of deep learning methods (convolutional neural networks or CNNs) and the increased availability of large data sets of face images with associated true and apparent ages (the latter estimated by people).

For our analysis, we use a machine-learning based software provided to us by Antipov, Baccouche, Berrani, and Dugelay (2016), which has been specifically developed for the problem of apparent age estimation. Their software is the winner of the 2016 Looking At People Apparent Age Estimation competition. We provide a detailed discussion of CNNs and the training steps associated with our software in Appendix D and provide a brief summary here. The software is based on the Oxford's Visual Geometry Group deep convolutional neural network architecture. In a first step, it has been pre-trained on more than 250,000 pictures with information on people's true age using the Internet Movie Database and pictures from Wikipedia. In a second step, it has been fine-tuned for apparent age estimation using a newly available data set of 5,613 facial pictures for which at least ten people estimated the person's age. Both the distribution of true ages used for pre-training and human age estimations used for software validation covers people from all age groups, including children and elderly people. The final output of the software is a 100×1 vector of probabilities associated with all apparent ages between 0 and 99 years. The apparent age point estimate is derived by multiplying each apparent age with its associated probability.

To carry out our analysis, we manually collect a large set of pictures of CEOs who were CEO of a *Fortune 500* firms in 2006. Note that the *Fortune 500* actually publishes 1,000 firms in their list each year, which generates an initial sample of of 1,000 CEOs. Collecting pictures based on the 2006 *Fortune* list not only allows us to exploit the substantial variation in CEOs' exposure to industry shocks induced by the 2007-2008 recession, but also prevents survivorship bias that we might introduce if we included CEOs from earlier years who left the CEO position a considerable amount of time before the recession. In the collection process, we aim for five pictures from the beginning of a CEO's tenure and two additional pictures every four years after that, all the way to present-day. We collect pictures from gettyimages.com as well as Google Images. For 466 CEOs, we are able to find at least two pictures from different points in time during or after their tenure. In total, we collect 3,113 pictures for these 466 CEOs; this set of pictures constitutes the main sample for the analyses below. We proceed in two steps. First, we document the *apparent* age

distribution based on the main picture sample and provide summary statistics. Second, we run a difference-in-difference regression to estimate the effect that stress—measured by industry shocks during the 2007-2008 recession—has on CEOs' apparent age.

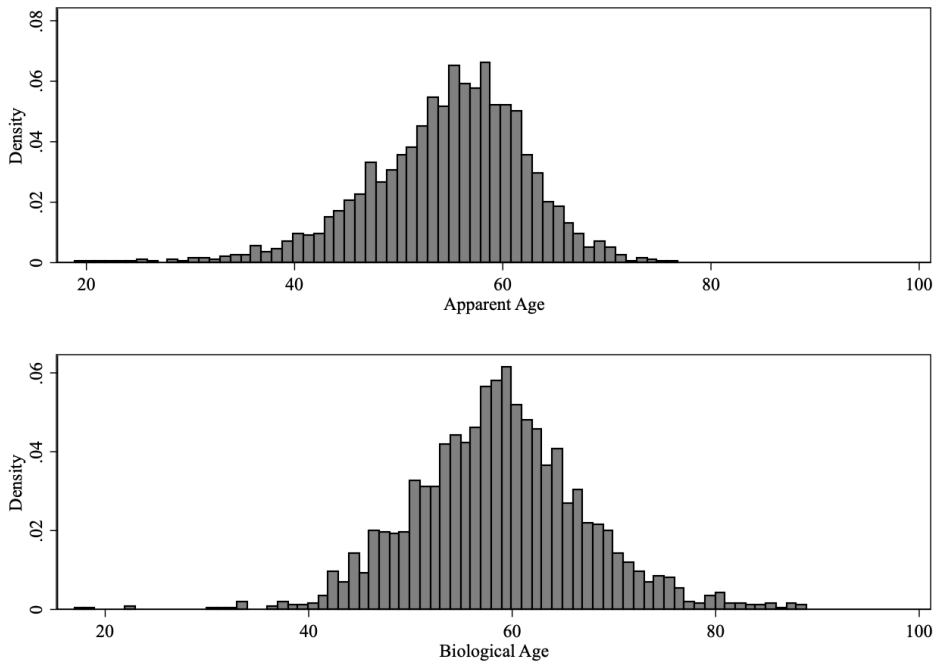

Figure 4 shows the age distribution of CEOs based on 3,113 collected pictures. The upper part shows the apparent age distribution, the lower part the associated biological age distribution. Both distributions are, reassuringly, highly correlated, though it appears that many CEOs look younger relative to their true age (i.e., the apparent age distribution is shifted to the left). The fact that, on average, the software estimates CEOs to look younger compared to their biological age might be unsurprising given that the age estimation software is targeted for the average population. CEOs, instead, are high SES people, have better access to health care, can afford healthier food, and live longer than the average population (see Table 1 and Chetty et al. 2016). We emphasize that all of our results below on the effect on industry shocks on CEO aging entail a *within-CEO* comparison and do not rely on comparisons between CEOs and the general population.

To illustrate the mechanisms we have in mind, we first zoom in on one specific CEO: James Donald, the CEO of Starbucks from April 2005 until January 2008, when he was fired.[37] Figure 5 shows two pictures of Donald; the one on the left was taken on December 8, 2004, i.e. before his CEO appointment at Starbucks; the one on the right on on Monday, May 11, 2009, i.e. after he was dismissed. Hence, the two pictures were taken 4.42 years apart. Donald was 50.76 years old in the first picture, and 55.18 years old in the second picture. The machine-learning based aging software predicts his age in the earlier picture at 53.47 years, and his age in the later picture as 60.45 years. Thus, for both pictures, the software thinks that he looks older than his true age. Moreover, the software estimates that he aged by 6.98 years, more than 2.5 years more compared to the actual time passed between the two pictures. We extend this analysis and search for pictures of James Donald from between three years before and after the onset of the crisis in 2007, i.e., between

[37] He was dismissed in January 2008 after Starbucks' stock had plunged by more than 40% during his last year of tenure.

Figure 4: CEO Apparent and Biological Age Distribution

This figure shows CEOs' apparent and biological age distributions. The first plot shows the distribution of CEOs' apparent age estimated using the machine-learning based age estimation software from Antipov, Baccouche, Berrani, and Dugelay (2016) for a sample of 3,113 pictures collected from *Fortune 500* CEOs who were CEO in 2006. The second plot shows the associated biological age distribution.

2004 and 2010. We are able to find a total of 20 pictures of him during these years. Consistent with the initial two pictures, we find that the mean difference between his apparent and biological age is 0.96 years prior to 2007, and increases to 4.97 years in or after 2007. The bottom half of Figure 5 summarizes these estimates in an event-study-type graph; the graph visualizes the jump in Donald's apparent versus biological age in 2007, and the continued aging effects after the crisis shock. In summary, this example nicely typifies our approach, especially in light of Donald's and Starbucks' struggles during his last year of tenure (see footnote 37).

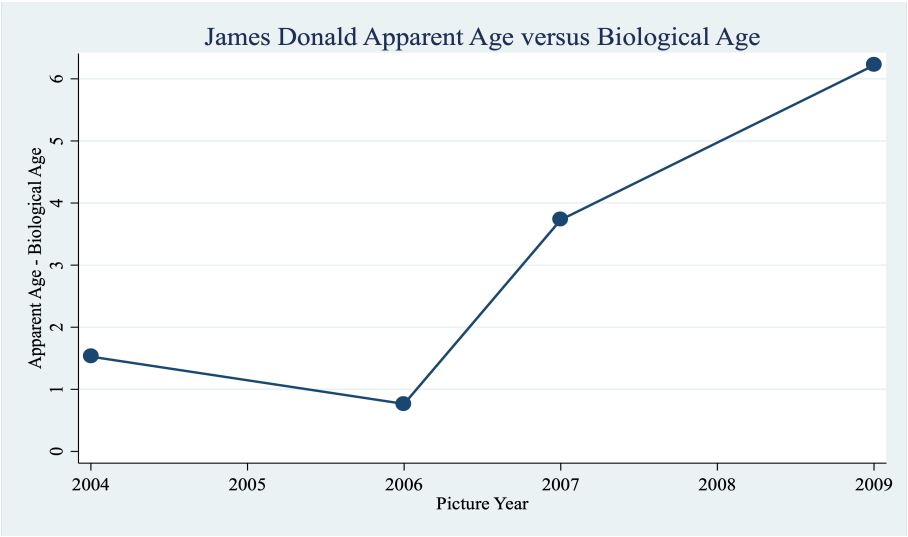

Table 5 shows summary statistics for the 466 CEOs for which we find at least two pictures. The average CEO is 56.35 years old in 2006, and the mean pre-2006 tenure is 8 years. On average, we are able to find about 7 pictures of a CEO (conditional on finding at least two pictures). The

Figure 5: Sample Pictures (James Donald, CEO of Starbucks from 2005 to 2008)

The first two pictures show James Donald, CEO of Starbucks from 2005 to 2008. Based on data from Ancestry.com, Donald was born on March 5, 1954. The picture on the left was taken on December 8, 2004, that on the right on Monday, May 11, 2009. Biological ages: 50.76 and 55.18 years, respectively. Apparent ages based on aging software: 53.47 and 60.45 years, respectively. The figure at the bottom shows how James Donald's apparent age compares to his true age over time based on 20 pictures collected between 2004 and 2009.

majority of CEOs head firms in the manufacturing; transportation, communications, electricity and gas; and finance industries.

Table 5: Summary Statistics

The table presents summary statistics of the CEOs for whom we find at least two pictures from different points in time during their tenure.

	PANEL A: CEO CHARACTERISTICS					
	N	mean	sd	p10	p50	p90
Biological Age in 2006	466	56.35	8.46	46	57	66
Pre-2006 Tenure	466	8.00	7.71	2	6	17
Pre-2006 Ind. Shocks	466	0.70	1.52	0	0	3
2007-2008 Ind. Shocks	466	0.81	0.78	0	1	2
2007-2008 Ind. Shocks (ITT)	466	0.96	0.81	0	1	2
No. of Pictures per CEO	466	6.68	4.41	2	6	12

	PANEL B: INDUSTRY DISTRIBUTION		
Industry (Number of CEOs)	Manufacturing (182)	Construction (12)	Mining (21)
	Wholesale (17)	Retail (53)	Services (44)
	Trans.; Commns.; Elec., Gas, and Sanitary Service (71)		
	Finance, Insurance, Real Estate (65)		Others (1)

We now formalize our analysis of job-induced aging by using the 3,113 collected pictures in a difference-in-difference design. Specifically, we test whether higher stress levels as a result of experiencing industry shocks during the recent financial crisis have detectable effects on how old CEOs look. We follow our approach in Section 4 and use 3-digit SIC codes as well as the 30% decline in equity value criterion to classify firms into industries and assign industry shocks. Our approach classifies 79 out of a total of 149 industries as experiencing an industry shock during years 2007 to 2008. We implement the difference-in-difference analysis using the following regression model:

$$ApparentAge_{i,t} = \beta_0 + \beta_1 \times BiologicalAge_{i,t} + \beta_2 \times IndShock \times TimeDummy + \beta_3 \times X_{i,t} + \delta_t + \theta_i + \varepsilon_{i,t}$$

where i represents each CEO and t represents each year. The *IndShock* variable is a dummy

variable indicating whether or not the CEO experienced industry shocks during 2007 to 2008 (either in 2007 or 2008, or in both years). We construct the *IndShock* variable in two ways. First, we check whether the CEO's firm operates in an industry that experienced shocks during 2007 to 2008 regardless of whether or not the CEO stepped down between 2006 and 2008. We call this version of constructing the industry shock experience the "intention-to-treat" (ITT) version. This version addresses concerns that the industry shock experience might be correlated with CEOs' decision to step down from their position, potentially introducing bias. Second, we check whether the CEO actually experienced industry shocks during 2007 to 2008, not counting industry shock years after a CEO already stepped down.[38] We call the second version the "instrumental variables" (IV) version, as we will use the ITT assignment as an instrument for actually experienced industry shocks to account for potential selection bias. Turning to the control variables, $X_{i,t}$, we include the number of industry shocks a CEO experienced before 2006 as well as CEO tenure up to year 2006. We also include CEO fixed effects (θ_i) and year fixed effects (δ_t). Note that these fixed effects absorb the main effects of *IndShock* and *TimeDummy* in the regression. The key coefficient of interest is β_2, indicating the difference in how old CEOs *look* in post-crisis years depending on whether or not they personally experienced industry shocks during 2007-2008.

Table 6 presents results of the difference-in-difference analysis. In column (1), we use the "intention-to-treat" version of the industry experience, interacted with a time dummy indicating whether the picture is is taken in 2007 or later, i.e. after the onset of the crisis. The coefficient on the interaction term is 1.067, significant at 5%, indicating that CEOs look around 1 year older during and post-crisis if they experienced industry shocks between 2007 and 2008 relative to if they did not. Column (2) shows the second-stage results when we use the ITT version of the industry shock experience interacted with the post-2006 dummy as an instrument for actual industry shock experience interacted with the post-2006 dummy. The coefficient on the interaction term is 1.166

[38]For example, if a CEO stepped down in year 2007 and the industry she was in experienced a shock only in 2008, the ITT version will generate her industry shock experience as 1 and the second version will generate it as 0.

and remains significant at 5%. The size the coefficient is very close to those in column (1). This reflects the fact that assigned and actual industry shock experience are highly correlated; the first-stage coefficient is 0.915 ($= \frac{1.067}{1.166}$), significant at 1%. In column (3), we split the post-period into two parts, one indicating whether the picture is from between 2007 to 2011 and the other indicating whether it is from after 2011. We find that the acceleration in aging as a result of experiencing industry shocks during the crisis becomes stronger over time. Our estimates imply an aging effect of about 0.9 years for the first five-year period, increasing to about 1.3 years in the 2012 and after period.

We further verify that our results are not affected by differential finding rates of pictures depending whether CEOs experienced distress during the crisis. For example, it could be the case that experiencing industry shocks makes CEOs more likely to step down earlier, which might make it more difficult to find more recent pictures. This could introduce selection bias. Appendix-Figure B2 depicts the average number of pictures per CEO we find in each year for the group of CEOs who experienced industry shocks between 2007 and 2008 and for the group that did not. In general, the finding rates closely follow each other over time, though we note a small divergence in finding rates between the two groups post 2015. Therefore, we repeat our analysis restricting our sample to 2000-2015, as shown in Appendix-Table B11. The size and significance of the coefficients on the interaction terms remain similar in all the three columns. All together, we find evidence that higher stress levels in the form of industry distress leave detectable signs of aging in CEOs' faces.

6 Conclusion

In this paper, we assess the health consequences associated with serving as CEO in harsher business environments. Exploiting the staggered introduction of Business Combination laws in different states over time, we document that CEOs who serve under stricter corporate governance regimes face poorer long-term health outcomes, reflected in an earlier age of death. We estimate

Table 6: Industry Distress and CEO Aging

Column (1) shows the results when we use the "intention-to-treat" (ITT) version of the industry shock experience interacted with the post-2006 dummy as the main independent variable. Column (2) shows the second-stage results when we use the ITT version of the industry shock experience interacted with the post-2006 dummy as an instrument for the actual industry shock experience interacted with the post-2006 dummy. Column (3) shows the results when we include both the interaction between the "intention-to-treat" industry shock experience and the dummy indicating whether the picture was taken during 2007 to 2011 and the interaction between the "intention-to-treat" industry shock experience and the dummy indicating whether the picture was taken after 2012. "*Pre*2006 *Ind*. *Shock*" and "*Pre*2006*Tenure*" are categorical variables whom we control for by including fixed effects. We weight observations by the inverse of the number of pictures collected for each CEO. Fixed effects are included as indicated at the bottom of the table. Standard errors are clustered at the industry level and shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively.

Observations	3,113	3,113	3,113

a six to eight percent difference in mortality rates as result of exposure to less stringent corporate governance. The effect is driven by the initial years of reduced monitoring; incremental health benefits taper off at higher levels of exposure to more lenient governance. To complement these

findings, we explore the health consequences of industry-wide distress shocks as a second shifter in a CEO's stress levels. In line with our initial results, we observe significant adverse health effects in terms of life expectancy for CEOs who experienced periods of industry-wide distress during their tenure.

We then analyze whether industry distress is also reflected in more immediate, non-mortal adverse health consequences, namely faster aging as gauged by machine-learning based age estimation software. We first document the apparent age distribution of CEOs based on a sample of 3,113 pictures from *Fortune 500* CEOs taken at different point of time during and after their tenure. Based on a difference-in-differences design that exploits variation in industry shock exposure during the financial crisis, we estimate that CEOs who experienced industry shocks during 2007 to 2008 look roughly one year older relative to had she experienced no industry shocks. The effect becomes slightly larger – up to 1.3 years – over time, i.e., if we base the "post-period" on more recent pictures.

Our results contribute to the research on managerial performance and incentives and, in particular, on the trade-offs between managerial incentives and private benefits arising from the separation of ownership and control. We document and quantify a previously unnoticed yet important cost, in terms of shorter longevity of the CEOs, associated with serving under strict corporate governance, i.e. a governance structure that is generally viewed as desirable. Our results suggest that one ought to take these hidden, potentially large costs into consideration when designing and evaluating contracts. The findings regarding the detrimental health effects of industry shocks underscore that independent of incentives and monitoring, periods of heightened stress and performance pressure can leave a visible and lasting imprint on CEOs in terms of adverse health outcomes.

We emphasize that other job situations apart from more stringent monitoring and industry distress might plausibly trigger adverse health outcomes as well, including corporate restructurings and layoffs.[39] Likewise, heightened workplace stress can also adversely likely affect other aspects

[39]For example, in a 2016 documentary titled "Lonely at the Top: Top-Level Managers at Their Limit" about the

of life, including CEOs' marriage and divorce rates as well as parenting.

job experiences of German executives, Brigitte Ederer, former member of the executive team at Siemens AG, recalled: "Laying people off is something that took its toll on me ... something I don't ever want to do again." The documentary is available (in German) on YouTube.

Appendix A Variable Definitions

Table A1: Variable Definitions

Variable Name	Definition
YearOfBirth	The birth year of a CEO.
DeadOct2017	A dummy variable indicating whether a CEO has passed away by October 1st, 2017.
DateOfDeath	The date of death of a CEO who has passed away by October 1st, 2017.
YearOfDeath	The year of death of a CEO, calculated up to the monthly level (e.g., 2010.5 for a person who dies on 6/30/2010).
Age Taking Office	A CEO's age when appointed as CEO.
Year Taking Office	The year in which a CEO is appointed.
$Age_{i,t}$	A CEO's age in year t.
$Tenure_{i,t}$	A CEO's cumulative tenure (in years).
$Tenure^2_{i,t}$	A CEO's squared cumulative tenure (in years).
$BC_{i,t}$	A CEO's cumulative exposure to a BC law during his tenure over time (in years).
$BC_{i,t}^{(\min\text{-}p50)}$	A CEO's below-median (4.4 years), cumulative exposure to a BC law during his tenure over time (in years).
$BC_{i,t}^{(p51\text{-}\max)}$	A CEO's above-median (4.4 years), cumulative exposure to a BC law during his tenure over time (in years).
$BC\ Dummy_{i,t}$	1 if CEO i is insulated from a BC law in year t.
$FL_{i,t}$	A CEO's cumulative exposure to the first-time enactment of a 2nd generation anti-takeover law (FL) during his tenure over time (in years).
$FL_{i,t}^{(\min\text{-}p50)}$	A CEO's below-median (4.4 years), cumulative FL law exposure during his tenure over time (in years).
$FL_{i,t}^{(p51\text{-}\max)}$	A CEO's above-median (4.4 years), cumulative FL law exposure during his tenure over time (in years).
IndDistress	1 if median two-year stock return (forward-looking) of firms in the 3-digit SIC-code industry is less than -30%.
$Year_{i,t}$	Year of a given subspell, used in hazard specifications when linearly controlling for time.
$Pay_{i,t}$	CEO i's total pay in year t (from Gibbons and Murphy (1992)).
$Assets_{j,t}$	Firm j's total assets in year t (from Compustat); data for years with missing information is interpolated.
$Employees_{j,t}$	Firm j's total number of employees in year t (from Compustat); data for years with missing information is interpolated.

Appendix B Appendix Figures and Tables

Figure B1: First-Time Introduction of Second-Generation Anti-Takeover Laws Over Time

This figure visualizes the distribution of first-time enactments of any of the five most common second-generation anti-takeover laws over time, i.e., Business Combination (BC), Fair Price (FP), Control Share Acquisition (CSA), Poison Pills (PP), and Directors' Duties (DD) laws. The graph omits the state of Hawaii, which adopoted a CSA law on 4/23/1985 and DD and PP laws on 6/7/1988.

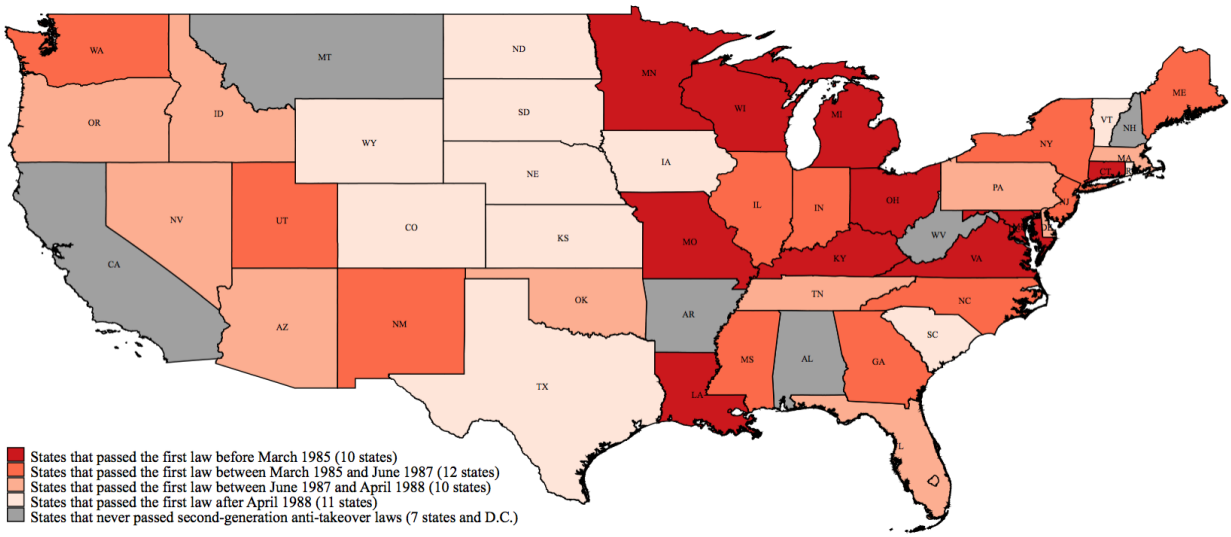

Figure B2: Average Number of Pictures per CEO Across Years

This figure depicts the average number of pictures per CEO we find each year for the group of CEOs who experienced industry shocks during 2007-2008 and for the group that did not. The two red vertical lines represent the years 2006 and 2008.

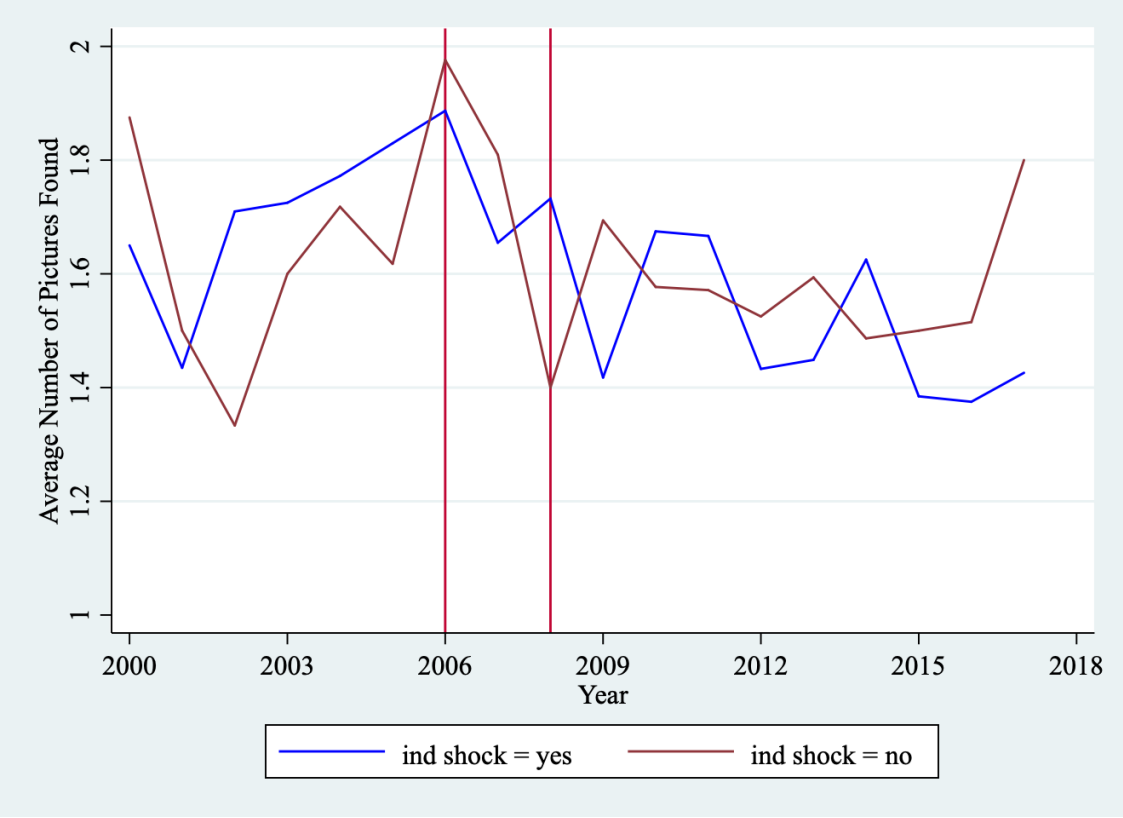

Table B1: Business Combination Laws and Tenure

This table presents hazard models predicting CEO departure using CEOs' exposure to BC laws. Fixed effects are included as indicated at the bottom of the table. Standard errors, clustered at the state of incorporation level, are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively. All variables are defined in Appendix A.

DEPENDENT VARIABLE: $CEO\ Departure_{i,t}$

Table B2: Hazard Model (Additional Controls)

This table is the same as Table 2a except that we include additional controls for CEO characteristics (pay) and firm characteristics (assets, employees). Fixed effects are included as indicated at the bottom of the table. Standard errors, clustered at the state of incorporation level, are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively. All variables are defined in Appendix A.

Table B3a: Hazard Model (First Law)

This table presents the results of the Cox (1972) proportional hazard model (Equations 1 and 2), using the first-time introduction of any of the five most common second-generation anti-takeover laws as a measure of lenient governance. Note that the number of CEOs is lower compared to Tables 2a and 2b. This is because we restrict to CEOs appointed in years prior to the introduction of the anti-takeover law(s) used in the analysis to alleviate selection concerns. Mechanically, a smaller set of CEOs passes this requirement when using the *First Law* introduction instead of the passage of a BC law. Fixed effects are included as indicated at the bottom of the table. Coefficients are reported as hazard ratios. Standard errors, clustered at the state of incorporation level, are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively. All variables are defined in Appendix A.

Table B5: Excluding Lobbying Firms, Opt-Out Firms, and Firms with Firm-Level Defenses

This table presents the results of the Cox (1972) proportional hazard model when we exclude lobbying firms, firms that opted out of the laws, or firm-years in which firms used firm-level defenses. In Panel A, we exclude 46 firms that Karpoff and Wittry (2018) identify as firms that lobbied for the enactment of coverage by the second-generation anti-takeover laws. In Panel B, we exclude 30 firms that opted out the second-generation anti-takeover laws, based on data from the Institutional Shareholder Services (ISS) Governance database. In Panel C, we exclude firm-years in which firms used firm-level defenses as identified from the the ISS data and data from Cremers and Ferrell (2014). Controls and fixed effects are included as indicated at the bottom of the table. Coefficients are reported as hazard ratios. Standard errors, clustered at the state of incorporation level, are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively.

Table B6: Restricting to Years After the First-Generation Laws (*Edgar v. MITE* Case)

This table presents the results of the Cox (1972) proportional hazard model for various splits of the data around 1982; Karpoff and Wittry (2018) argue for analyzing the period from 1982 onwards since the first-generation anti-takeover laws lost their effect only in June 1982 after the *Edgar v. MITE* ruling. In Subsample A, we restrict our sample to the years 1982 and after. In Subsample B, we restrict to CEOs who stepped down in or after 1982. In Subsample C, we restrict to CEOs who were appointed in or after 1982. Fixed effects are included as indicated at the bottom of the table. Coefficients are reported as hazard ratios. Standard errors, clustered at the state of incorporation level, are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively.

Table B7: Excluding DE or NY Incorporated, Banking, or Utility Firms

This table presents the results of the Cox (1972) proportional hazard model estimation when we exclude firms based on state of incorporation or industry affiliation. In Panel A, we exclude firms that are incorporated in Delaware or New York (the two most common states of incorporation in our sample, see Table 1). In Panel B, we exclude firms that are classified as "Banking" firms based on the Fama-French 49 industry classification. In Panel C, we exclude firms that are classified as "Utilities" based on the Fama-French 49 industry classification. Controls and fixed effects are included as indicated at the bottom of the table. Coefficients are reported as hazard ratios. Standard errors, clustered at the state of incorporation level, are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively.

Table B8: Industry Distress and Tenure

This table presents hazard models predicting CEO departure using CEOs' exposure to industry distress and controlling for their exposure to BC laws. Panel A presents the results for the main sample. Panel B presents the results for the extended sample including CEOs who were appointed after the passage of BC laws. Fixed effects are included as indicated at the bottom of the table. Standard errors, clustered at the state of incorporation level, are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively. All variables are defined in Appendix A.

Table B10a: Hazard Model (Industry Distress, Additional CEOs)

This table is the same as Table 4a except that it is estimated on the extended sample includign CEOs who were appointed after the passage of BC laws. Fixed effects are included as indicated at the bottom of the table. Coefficients are reported as hazard ratios. Standard errors are shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively. All variables are defined in Appendix A.

Table B11: Industry Shock and CEO Aging: Restricted Sample 2000-2015

The table shows the results of the picture analysis in Section 5.1 when we restrict the sample to 2000-2015 pictures. Column (1) shows the results when we use the "intention-to-treat" (ITT) version of the industry shock experience interacted with the post-2006 dummy as the main independent variable. Column (2) shows the second-stage results when we use the ITT version of the industry shock experience interacted with the post-2006 dummy as an instrument for the actual industry shock experience interacted with the post-2006 dummy. Column (3) shows the results when we include both the interaction between the "intention-to-treat" industry shock experience and the dummy indicating whether the picture was taken during 2007 to 2011 and the interaction between the "intention-to-treat" industry shock experience and the dummy indicating whether the picture was taken after 2012. "*Pre*2006 *Ind. Shock*" and "*Pre*2006*Tenure*" are categorical variables whom we control for by including fixed effects. We weight observations by the inverse of the number of pictures collected for each CEO. Fixed effects are included as indicated at the bottom of the table. Standard errors are clustered at the industry level and shown in brackets. *, **, and *** denote significance at the 10, 5, and 1 percent level, respectively.

DEPENDENT VARIABLE: *Apparent Age*

Appendix C Tenure Controls and Selection Bias

We run our hazard models with and without tenure. The evidence shows that anti-takeover laws significantly increased the tenure of incumbent CEOs (which is consistent with reduced stress on the job). We would like, however, to isolate the effects of the corporate governance laws on working conditions from any possible effects of the longer tenure. Adding controls for tenure serves this purpose, at the cost of the introduction of selection bias. Here, we discuss the intuition for the bias and its likely sign. To simplify the discussion, assume that there are two tenure lengths, Long and Short. When we condition on a given tenure we estimate:

$$E[Lifespan_{BC}|Tenure_{BC} = Long] - E[Lifespan_{NoBC}|Tenure_{NoBC} = Long]$$

The selection problem arises because of the difference in the conditioning statements, which is to say, the composition of CEOs with Long tenure changes with the business combination laws. (The choice of Long in the conditional does not matter for the discussion.) Since the BC laws push people from Short tenure into Long, the bias will be a function of the life expectancy of the Long-only-under BC group relative to the always-Long group.[40] This can be seen by adding and subtracting our desired counterfactual:

$$\overbrace{E[Lifespan_{BC} - Lifespan_{NoBC}|Tenure_{BC} = Long]}^{\textbf{Causal Effect of BC Laws}} - \underbrace{[E[Lifespan_{NoBC}|Tenure_{BC} = Long] - E[Lifespan_{NoBC}|Tenure_{NoBC} = Long]]}_{\textbf{Selection Bias from Endogenous Control}} \quad \text{(B1)}$$

Although we cannot observe $E[Lifespan_{NoBC}|Tenure_{BC} = Long]$, this statement can inform us about the likely direction of the bias.

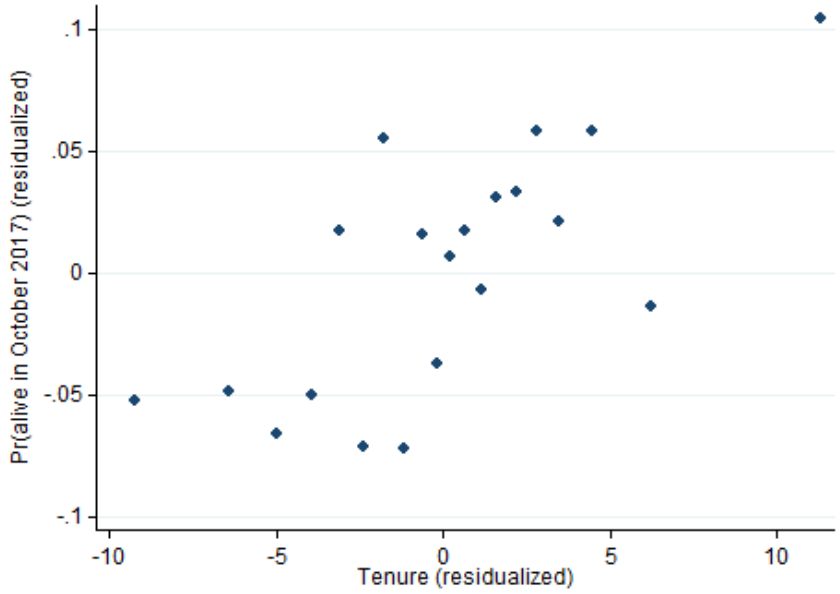

The direction of the bias depends on whether we are adding relatively long- or short-lived CEOs the Long tenured group. Although we cannot directly observe the switchers, we can examine the relationship between tenure and longevity for some guidance as to the direction of bias. Appendix Figure C1 plots the relationship between tenure and lifespan for the CEOs in our sample, where we control for a CEO's birth year and age at appointment as well as firm location and industry affiliation. Panel (C1a) depicts the entire sample and panel (C1b) shows the CEOs who are not exposed to BC laws. We see that there is a positive correlation between tenure and life expectancy in the full sample which grows weaker but is still present in the group of CEOs who do not serve under the business combination laws. If the CEOs who have their tenure lengthened by the business combination laws have shorter life expectancy than those who would have had Long tenure in either regime, then the bias term will be negative, and our results will be attenuated. This direction of bias would be consistent with the overall tenure-life expectancy relationship. In particular, it would be consistent with a story in which some CEOs who did not have the protection of the business combination laws were induced to retire by diminished health capital.

[40] This assumes monotonicity, which is to say that no CEO reduces their tenure as a result of the business combination laws.

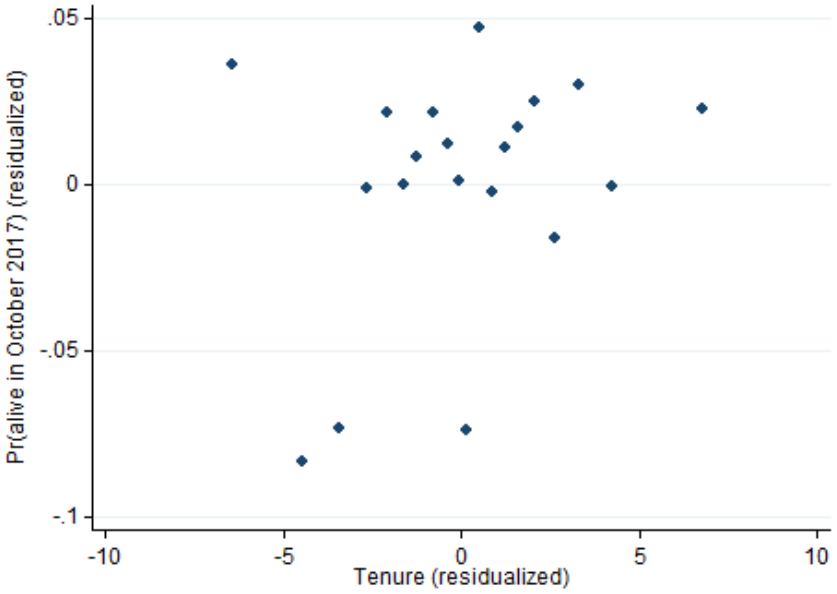

Figure C1: Tenure and Lifespan

This figure shows binned scatterplots of the relationship between tenure and lifespan, obtained from a regression of an indicator variable that is 1 if a CEO is still alive as of the censoring date on CEO tenure. The regression uses either the full sample (Panel A) or restricting to CEOs without BC exposure (Panel B). The estimation includes birth year fixed effects, fixed effects for CEO age at appointment, location fixed effects, and industry fixed effects; i.e., both the x-axis and y-axis display residualized variables.

(a) Main Sample ($N = 1,605$)

(b) Main Sample Restricted to CEOs Without BC Exposure ($N = 980$)

Appendix D Age Estimation Software Details and Convolutional Neural Networks

Apparent Age Estimation:

- Different from biological age estimation
- min $f(EstAge - ApparentAge)$ vs. min $f(EstAge - TrueAge)$

ML Implementation:
Oxford's Visual Geometry Group deep convolutional neural network architecture

1. Pre-processing step: detect faces in images and resize to 224x224
2. Pre-training step: train for biological age using 250,367 IMDB-Wiki pictures (training time: 1.5 days)
3. Training and validation step: fine-tune for apparent age using 5,613 "age-annotated" pictures with ≥ 10 human age estimations per picture (training time: 5 hours)
    - 11-fold cross-validation (11 sub-models)
4. Run on test data (CEOs, politicians, ...)

Convolutional Neural Network:

- **Input:** 224x224x3 array of pixel values (x3 is color, RGB)
- **Convolutional layer:** Flashlight (aka filter, neuron, kernel) sliding (aka convolving) around input image
    - Say, dimension of 5x5x3: each neuron in conv layer has 75 connections to input volume
    - Can use more than one filter: increases output volume
- **Pool layer:** Downsampling along spatial dimensions
- **Fully-connected layer:** Transformation of previous layer into N-dimensional output vector ($N = 100$)
- **Output:** $p_i, i \in \{0, 99\}$ are probabilities of apparent age = i years
