PRELIMINARY DRAFT

Task Mismatch and Salary Penalties: Evidence from the Biomedical PhD Labor Market*

Holden A. Diethorn† Gerald R. Marschke‡

August 3, 2021

Abstract

In this paper, we offer a conceptual framework linking the task histories of workers to their current salaries, the main result being that workers with human capital acquired from past training and employment that is relevant to tasks performed in current employment earn a premium relative to other workers of the same years of general experience. We explore the special case of the biomedical PhD labor market where task-mismatch is likely common as around 70% of new doctorates pursue postdoc training, but only one-in-seven obtain a tenure-track research position in academia, the remainder ending up in non-tenure-track academic, industry, government, and nonprofit sector careers. Using representative, longitudinal survey data we show that postdocs lead to lower earnings on average, though a higher likelihood of a tenure-track academic position. These findings are robust to plausible levels of selection bias. The data permit us to measure both the returns to task-specific human capital and the salary effects of mismatch between task-specific human capital and tasks performed on the job. For example, the data show a 15.8% postdoc salary penalty in industry, the largest postdoc penalty by sector. We show that this penalty is fully explained by skill-task mismatch, and directly rule out that the penalty is the result of differences in ability at the time of PhD completion, a compensating differential for conducting research or performing other job tasks as part of current employment, or sorting across different types of firms and occupations. Postdocs appear to raise salaries in academic careers, especially for non-tenure-track academic jobs, where the skills learned in the postdoc closely match job tasks, which are heavily weighted towards research. Our results suggest that the task-skill match is the main driver of salary differences between employed biomedical doctorates with and without postdoc training. We discuss the implication of these findings for the rationality of pursuing postdoctoral training. (*JEL* J24, J31, I26, J44)

1 Introduction

Biomedical research is a significant source of knowledge creation and innovation in the United States, with much of this research being conducted by the graduate students and postdoctorates ("postdocs") that staff the labs of research faculty (Freeman et al., 2001*a*,*b*; Stephan, 2012; Alberts et al., 2014).[1] Since 1980, the number of new biomedical science PhDs awarded by US universities has more than doubled (Figure A.1), with around 70% of each cohort going on to work as postdoctoral researchers for an average duration of five years (Figure A.2).[2] Postdoc training is typically viewed as necessary for obtaining a tenure-track research position in biomedical science, with the postdoc-trained share of both new tenure-track and newly-tenured biomedical research faculty hovering around 90% since 1993 (Figure A.3 and Figure A.4, respectively). However, most biomedical postdocs are unlikely to obtain a tenure-track position in academia, with less than 20% of biomedical PhDs who graduated in 2005 working as a tenure-track researcher within 10 years of graduation (Figure A.5).[3]

With a significant share of biomedical postdocs working outside academia, the National Academies of Sciences, Engineering, and Medicine have called for a broadening of the skills emphasized in postdoctoral training, noting that the current set of tasks performed as part of postdoc training may do little to build the skills necessary for success in nonacademic

[1]Biomedical research expenditures represented 18% of all academic R&D expenditures in 2016 at just over 13 billion dollars (Appendix Table 5-4 of National Science Board (2018)). Life scientists produced almost half of all US university-based patents in 2016, with Pharmaceuticals, Biotechnology, and Medical Technology representing the top three technology areas covered by US university-based patents in 2016, each having grown at an average annual rate of 18%, 8%, and 16%, respectively, since 2011 (Appendix Table 8-2 of National Science Board (2018)). The number of scientific articles published in biomedical science in each year has typically grown over time, from about 63,000 in 2003 to 73,000 in 2016, having peaked in 2014 at 82,000 articles published in that year (Appendix Table 5-30 of National Science Board (2018)). This growth in patenting and scientific output has taken place in spite of decreases in inflation-adjusted National Institutes of Health (NIH) funding since its peak in FY 2003 (Figure 1 in Johnson and Sekar (2019)).

[2]Descriptive figures are based on data from the National Science Foundation's (NSF's) Survey of Doctorate Recipients (SDR) linked with the NSF's Survey of Earned Doctorates. See Section 2 for additional details.

[3]See Stephan (2012) for a recent and comprehensive view of the scientific research environment, including the role played by postdoctoral researchers. Members of the biomedical research community have expressed concern that the small chance of a young biomedical scientist achieving a career as an independent researcher in academia, even after a prolonged period of postdoctoral training, hampers their ability to attract the best and brightest students to the field (National Research Council, 1998, 2005; National Academies of Sciences, Engineering, and Medicine, 2018; National Academy of Sciences, 2014; Alberts et al., 2014, 2015; Kimble et al., 2015; Daniels, 2015; Pickett et al., 2015).

careers (National Research Council, 2005; National Academies of Sciences, Engineering, and Medicine, 2018).[4] Out of common concern, the National Institutes of Health (NIH) launched the Strengthening the Biomedical Research Workforce program in 2013, awarding 17 Broadening Experiences in Scientific Training (BEST) awards to universities in support of new programs aimed at enhancing the training opportunities and career guidance available for biomedical graduate students and postdoctoral researchers.[5] The recommendations of the National Academies and the NIH BEST initiatives reflect the view that postdoc training in biomedical science is specialized academic training that develops a set of skills distinct from those obtained on-the-job in industry. In economics parlance, postdoc training, rather than being viewed as an investment in general human capital, is viewed as an investment in task-specific human capital, where the tasks emphasized are those most valued in academia, irrespective of their value in nonacademic employment.

A burgeoning literature in economics views skill as multidimensional, jobs as sets of tasks to be performed ("task requirements"), and the accumulation of human capital as task-specific.[6] Previous research finds that job task requirements are predictive of worker wages even when controlling for education and occupation (Autor and Handel, 2013; Deming and Kahn, 2018) and that task-specific human capital accumulation is a key source of wage growth over the life-cycle (Gathmann and Schönberg, 2010; Sanders, 2016; Lise and Postel-Vinay, 2020; Guvenen et al., 2020).[7] Given this previous research showing the importance of both a current job's task requirements and a worker's previously accumulated task-specific

[4] "The focus of young scientists on securing an academic research faculty position can lead them to overlook opportunities as independent researchers in other areas, such as in start-up and established industries, foundations, and government. Significantly, these opportunities may require training experience different from those associated with traditional academic careers. Yet too many postdoctoral researchers pursue training experiences with the objective of later securing an academic position, rather than enhancing their ability to compete for the range of fulfilling, independent careers that exist outside of academia, where the majority will be employed" (National Academies of Sciences, Engineering, and Medicine, 2018).

[5] For more information, see `https://commonfund.nih.gov/workforce`, Meyers et al. (2016), and Lenzi et al. (2020).

[6] See Sanders and Taber (2012) for a review of this literature and the related literature on industry-specific (or sector-specific) and occupation-specific human capital.

[7] In related work, Deming and Noray (2020) find that that the rate of change in the task requirements of jobs is important in explaining differences in the age-earnings profiles of STEM workers in different fields.

human capital to wage determination, we might expect that purported differences in the tasks emphasized as part of postdoctoral training versus industry employment to manifest in within-cohort salary differences between postdoc-trained and nonpostdoc-trained biomedical doctorates working in industry.

In this paper, we formalize the above intuition by offering a simple conceptual framework relating task-specific human capital to wage determination where within-cohort salary differences between postdoc-trained and nonpostdoc-trained biomedical doctorates in industry follows as a likely result, even after controlling for differences in ability at time of PhD graduation. We then utilize microdata from the Survey of Earned Doctorates (SED) linked to the longitudinal Survey of Doctorate Recipients (SDR) to explore the effect of postdoctoral training on the career trajectories of biomedical doctorates, with a focus on the extent to which differences in task-specific human capital may explain the observed within-cohort salary differences between postdoc-trained and nonpostdoc-trained biomedical doctorates working in industry.

To measure salary differences between postdoc-trained and nonpostdoc-trained biomedical doctorates, we estimate a Mincer (1974) human capital earnings function where an indicator variable for postdoc-trained status serves as the main variable of interest and where we control for a vector of individual-level characteristics, a quartic polynomial in experience, PhD university (i.e., *alma mater*) fixed effects, and field-by-cohort fixed effects. When experience is defined as the number of years since PhD graduation, we find that ex-postdocs working in industry are paid 15.8% less than their nonpostdoc-trained counterparts, but that ex-postdocs working in academia are paid no differently than biomedical doctorates without previous postdoc training. The existence of a postdoc salary penalty in industry is robust to plausible levels of selection on unobservable ability at time of PhD; via the estimation of bias-adjusted treatment effects à la Oster (2019), we find that the estimated 15.8% postdoc salary penalty represents a lower-bound for the causal impact, with an estimated upper-bound of 26.2%, which is consistent with previous research suggesting that

biomedical doctorates who pursue postdoc training are typically of higher ability at time of graduation (Sauermann and Roach, 2016). We find no evidence that the postdoc salary penalty in industry is the result of a compensating differential for conducting research — or any other task — as part of the doctorate's current job, nor do we find evidence that it is due to differential sorting of postdoc-trained and nonpostdoc-trained biomedical doctorates across different types of firms and occupations.[8]

However, we find evidence consistent with a task-specific human capital model of wage determination where within-cohort salary differences between biomedical doctorates with and without previous postdoctoral training is the result of differences in the task-specific human capital accumulated as part of postdoctoral versus industry employment. First, we find that detection of a postdoc salary penalty in industry depends crucially on the definition of experience as the number of years since PhD graduation; when experience is instead defined as the number of years of post-PhD employment in nonpostdoc positions, the magnitude of the estimated postdoc salary shrinks by over 70% and is statistically insignificant.[9] Second, we find substantial differences in the type of work activities performed as part of postdoc training versus industry employment: we find that most postdocs are primarily focused on basic research during postdoctoral training, while nonpostdoc-trained biomedical doctorates working in industry are more likely to be focused on applied research, professional services, management, or development during their first six years post-PhD. Third, we find that including task history variables as mediating regressors yields a statistically insignificant estimate of the effect of postdoc training on industry salary, with the estimated magnitude roughly one-third that of the baseline estimate. Altogether, these results suggest

[8] In fact, controlling for the tasks performed as part of the current job, as well as employer characteristics and occupation, increases the estimated magnitude of the postdoc salary penalty in industry.

[9] When experience is defined in this way, measured experience is set equal to one for both an ex-postdoc entering industry directly after their postdoc and a nonpostdoc-trained biomedical doctorate entering industry directly after graduation. Measuring experience in this way treats postdoctoral training as a type of schooling rather than as labor market experience. In a Mincer human capital earnings function, years of work experience are included to capture the effect of "productivity-augmenting investments in human capital" that continue after the completion of schooling and result in the accrual of skills on-the-job (Mincer, 1974; Autor and Handel, 2013).

that differences in accumulated task-specific human capital are important in explaining the differences in the salary of postdoc-trained and nonpostdoc-trained biomedical doctorates working in industry.

Along with contributing to the literature on the importance of task-specific human capital to wage determination, this paper also adds to a small but growing economic literature exploring the relationship between postdoctoral training and future career outcomes. Heggeness et al. (2018) estimate the impact of receiving an NIH postdoctoral fellowship on the probability of acquiring future NIH funding by utilizing a matching approach that compares NIH postdoctoral fellowship recipients with similar applicants whose proposals received a similar score but whom did not receive the fellowship. They find that securing an NIH postdoctoral fellowship improves a biomedical doctorate's chances of receiving future NIH funding, including R01 research project funding which signifies achievement of an independent research career. The findings in Heggeness et al. (2018) are similar in spirit to earlier work by Jacob and Lefgren (2011) who use a fuzzy regression discontinuity design based on NIH postdoctoral fellowship application scores and find that receipt of a postdoc fellowship is associated with a 20% increase in publications relative to non-recipients in the five years following fellowship receipt. Su (2013) finds that tenure-track or tenured faculty at more prestigious universities were more likely to have completed postdocs relative to faculty from less prestigious institution, but that the length of one's postdoc position was not associated with academic placement.

The empirical work in this paper is closest to that of Kahn and Ginther (2017) who use the SDR to examine how postdoc training impacts the salary of biomedical doctorates up to 15 years post-PhD after controlling for field of study, PhD cohort, and sector of employment. Kahn and Ginther (2017) find that postdoctoral training is associated with an increased probability that a doctorate ends up in a research-based academic career at 10 years post-PhD, but that doing a postdoc results in lower salary ten or more years post-PhD, regardless of employment sector. This paper follows Kahn and Ginther (2017) in finding that

ex-postdocs face a salary penalty in industry and that postdoc training is associated with greater chances of working in a research-focused job in academia and industry.[10] However, we find no evidence of a postdoc penalty on future salary in academia as whole, and instead find heterogeneity across different subsectors within academia.[11] Differences in results are likely explained by differences in empirical approaches: most significantly, this paper estimates the impact of doing a postdoc on *after-postdoc* salary by excluding from the analytical sample observations corresponding to years when a biomedical doctorate is employed as a postdoc. In addition to allowing us to explicitly consider the relationship between postdoc training and *future* salary in the absence of its effect on current salary, this approach also allows us to group person-year observations by the employment sector associated with each observation, rather than with the employment sector of the doctorate at a single point in time.[12]

The remainder of the paper is structured as follows: Section 2 describes the survey microdata used for the empirical analysis and presents descriptive evidence of a persistent life-cycle postdoc salary penalty for biomedical doctorates working in industry. Section 3 presents a model where salary differences between workers emanate from differences in both endowed and accrued task-specific human capital, the latter of which is a function of employment history. Section 4 lays out the empirical approach for our main analysis and Section 5

[10]We find that biomedical doctorates with postdoc training are 26.5 percentage points more likely to work in an academic research job and 21.3 percentage points more likely to obtain a tenure-track research position. Meanwhile, for biomedical doctorates working in industry, we find that postdoc-trained biomedical doctorates are about 12.3 percentage points more likely to obtain a research position within industry compared to their counterparts without postdoc training. "Research job" includes jobs where the primary activity is one of the following: basic research, applied research, development, or design. In all cases, the corresponding Oster (2019) bias-adjusted treatment effects are within a standard error of the original estimates, suggesting that these results are robust to selection on unobservables.

[11]Consistent with Kahn and Ginther (2017), we find evidence that postdocs earn less than their nonpostdoc-trained counterparts working in tenure-track research positions, though it is rare for a nonpostdoc-trained biomedical scientist to obtain a tenure-track research position. Meanwhile, we find that postdoc training is associated with a 15.9% increase in salary for those working as non-tenure-track researchers in academia, in contrast to Kahn and Ginther (2017) who find evidence suggesting that ex-postdocs earn less than nonpostdocs in this academic subsector. Lastly, unlike Kahn and Ginther (2017), we find no differences in salary for postdoc-trained and nonpostdoc-trained biomedical doctorates working in nonresearch positions in academia. These results are for regressions where experience is defined as years since PhD graduation, as in Kahn and Ginther (2017).

[12]Job switching is more likely to contaminate results when sector subsamples are constructed based on the employment sector at a single point in time.

reports the results, including estimation of Oster (2019) bias-adjusted treatment effects to test the robustness of results to selection on unobservable ability at time of PhD graduation. Section 6 considers various mechanisms that could plausibly lead to a postdoc salary penalty in industry, finding no evidence that it is the result of differences in current job tasks or employer characteristics, but instead is explained by differences in accrued task-specific human capital proxied by measures of the history of tasks performed as part of previous employment. Section 7 concludes.

2 Data

To construct a longitudinal dataset of biomedical doctorates, we append all waves of the NSF's Survey of Doctorate Recipients from 1993-2017. The SDR is a biennial survey of a representative sample of Science, Engineering, and Health (SEH) doctorates under the age of 76 and contains information on each doctorate's salary, employment sector, and whether their current employment is as a postdoc, in addition to many demographic and economic variables.[13] For doctorates in the constructed longitudinal SDR 1993-2017 dataset, we pull any additional information regarding postdoc employment available in earlier SDR waves (1973-1991) using the 1991 SDR Longitudinal File. We then merge this dataset with the NSF's Survey of Earned Doctorates (SED), which is an annual survey given to all PhD recipients from US institutions and which contains, among other information, each PhD recipient's field of study and whether he/she intended to take a postdoc position after graduation.[14] We follow a similar strategy to that of Kahn and Ginther (2017) in determining whether an individual has ever been employed as a postdoc and for how many years.[15] We limit the sample to those doctorates obtaining a PhD sometime between 1981 and 2007, who

[13]The SDR only contains information on doctorates graduating from US universities. Stephan (2012) reports that almost five out of ten postdocs in the US earned a doctorate in another country — we are unable to analyze the impact of postdoc-training for these doctorates using the SDR. For more information about the SDR see: `https://www.nsf.gov/statistics/srvydoctoratework/#sd`.

[14]The microdata described here are restricted-use and so were accessed remotely through the National Opinion Research Center (NORC) data enclave.

[15]See Appendix B.1 for details.

were first surveyed in the SDR prior to 2010, and for whom we could identify, for each year, whether they were employed as a postdoc.[16]

We use this data in Appendix B.2 to describe the demographic differences between postdocs and nonpostdocs, the salary and hours requirements associated with postdoctoral training, and the differences in subsequent career paths between postdoc-trained and nonpostdoc-trained biomedical doctorates.[17] One descriptive figure of particular interest is Figure 1 which shows the median salary of biomedical doctorates in academia and industry by postdoc-trained status and years since PhD graduation.[18] As expected, postdoc-trained biomedical doctorates in industry and academia have similar median salary and are paid less than nonpostdoc-trained biomedical doctorates in their first three years after PhD, which is when most would be employed as postdocs. Also as expected, industry salary profiles are steeper than academic salary profiles, indicating stronger salary growth in that sector. Interestingly, it appears that the median salary of ex-postdocs catches up with and then begins to exceed the median salary of nonpostdocs in the academic sector 10 years after graduation, which may be due to ex-postdocs being more likely to obtain higher-paying tenure-track research positions after postdoctoral training. In industry, it appears that the gap between the median salary of postdoc-trained and nonpostdoc-trained biomedical doctorates is persistent. This suggests that the cost of doing a postdoc for those that end up going to industry is not just forgone salary during their years as a postdoc, but also lower after-postdoc salary,

[16]In 2010, the SDR began sampling US-trained PhDs who reside outside of the United States, whereas previous waves only included US-trained PhDs residing in the US after graduation. Due to this sampling change, the NSF recommends caution when analyzing and interpreting pre- and post-2010 trends. Also, the SDR 2010 introduced new sample members that had graduated as far back as 2001; we are not able to reliably identify whether these individuals were ever employed as postdocs given that they are first sampled in the SDR many years after graduation and were not part of the SDR 2006 wave where doctorates were asked whether they had previously worked as a postdoc. We therefore restrict the sample to those first appearing in the SDR data prior to 2010. We also limit the sample to individuals who appear in the SDR in 1993 at the earliest due to survey format changes in 1993 and sampling changes in 1991. See `https://nsf.gov/statistics/srvydoctoratework/#micro&tabs-1&sd` for more details.

[17]This data is also used to produce the figures referenced in Section 1.

[18]Biomedical doctorates are associated with the employment sector (academia or industry) that they occupy at 10 years post-PhD. Observations are for biomedical doctorates first appearing in the SDR 1993, 1995, and 1997 waves and who graduated no earlier than 1990; due to the biennial nature of the SDR, we plot salary in 3-year intervals to ensure sufficient cell size.

possibly due to deferred task-specific human capital accumulation in tasks that are valued in industry but not emphasized as part of postdoctoral training. To formalize this intuition, in Section 3 we offer a simple task-specific human capital model of wage determination to serve as a conceptual framework for analyzing salary differences between postdoc-trained and nonpostdoc-trained biomedical doctorates working in industry.

3 Conceptual Framework

We first consider a general model with J tasks, K sectors, and I worker types.[19] In this model, differences in wages between different types of workers in a given sector result from two sources: 1) differences in endowed task-specific human capital and 2) differences in accrued task-specific human capital arising from differences in the employment history of different worker types. We then apply the results from this model to a special case with 2 tasks (research and nonresearch), 2 sectors (academia and industry), and 2 worker types (postdoc-trained and nonpostdoc-trained biomedical doctorates). We find that researchers estimating salary regressions are likely to find that postdoc-trained and nonpostdoc-trained biomedical doctorates are paid differently in industry, even if able to adequately control for differences in pre-existing abilities, due to differences in the tasks performed as part of postdoctoral training versus industry employment.

3.1 Model with J Tasks, K Sectors, and I Worker Types

We construct a model similar to Autor and Handel (2013) and Gathmann and Schönberg (2010) to motivate a task-based analysis of wage determination. We write worker i's stock of skills at time t as $\Phi_{it} = \{\phi_{it}^1 \dots \phi_{it}^J\}$ where each $\phi_{it}^j > 0$ gives worker i's stock of task j specific human capital at time t which is measured in the units of task j that worker i can

[19] More generally, K could represent the number of jobs or occupations in an economy. We use K to represent the number of employment sectors since our empirical analysis involves estimating separate salary regressions by employment sector, rather than by jobs or occupations.

perform in a unit of time ("task efficiency"). Assume worker i produces output in sector $k \in \{1, \ldots, K\}$ by utilizing task-specific skills ϕ_{it}^j for $j \in \{1, \ldots, J\}$ as follows:

$$Y_{ikt} = e^{\alpha_k + \sum_j \lambda_k^j \phi_{it}^j}, \tag{1}$$

where $\lambda_k^j \geq 0 \; \forall \; j, k$ measures the productivity of task j in producing output in sector k. As in Autor and Handel (2013), we normalize the output price for each sector to unity, and also note that α_k is not constrained to be positive, thus allowing for a worker's marginal productivity in sector k to be negative in the case of insufficient skills (e.g., an untrained air pilot).

If workers are paid their marginal product, then the log wage of worker i in sector k is:

$$w_{ikt} = \alpha_k + \sum_j \lambda_k^j \phi_{it}^j. \tag{2}$$

We write task j specific human capital as the sum of endowed task j specific ability and task j specific human capital accrued over time (e.g., through schooling or labor market experience):

$$\phi_{it}^j = H_i^j + H_{it}^j. \tag{3}$$

Then plugging (3) into (2) we get:

$$w_{ikt} = \alpha_k + \sum_j \lambda_k^j H_{it}^j + \sum_j \lambda_k^j H_i^j. \tag{4}$$

which shows that wage inequality among workers in sector k is the result of differing levels of endowed and/or accrued task-specific human capital.[20]

As in Gathmann and Schönberg (2010), assume task j specific human capital accrual is

[20]We note that it is possible that differences in task-specific human capital do not lead to differences in wages, depending on the relative productivity of each task j in production of output in sector k; that is, differences in task-specific human capital could be perfectly offset by differences in the productivity of each task.

the result of passive learning-by-doing as part of previous employment,[21] with the rate of task j specific human capital accrual varying by sector such that:

$$H_{it}^{j} = \sum_{k'} H_{ik't}^{j} \quad \text{where} \quad H_{ik't}^{j} \equiv \theta_{k'}^{j} t_{ik't} \tag{5}$$

where $k' \in K$ indexes sectors of *previous* employment and thus $t_{ik't}$ denotes worker i's previous years of experience working in sector k' and $\theta_{k'}^{j}$ denotes the amount of task j specific human capital accrued per each unit of time previously employed in sector k'. Substituting (5) into (4), we get:

$$w_{ikt} = \alpha_k + \sum_{j} \lambda_k^j \sum_{k'} \theta_{k'}^{j} t_{ik't} + m_{ik}. \tag{6}$$

where $m_{ik} = \sum_j \lambda_k^j H_i^j$ represents worker-sector match quality.[22]

3.2 Example with 2 Tasks, 2 Sectors, and 2 Worker Types

Suppose that there are two tasks: research (R) and nonresearch (N). Also suppose there are two sectors: academia (A) and industry (I). Then equation (6) can be written as:

$$w_{ikt} = \alpha_k + \lambda_k^R \left[\theta_{A'}^{R} t_{iA't} + \theta_{I'}^{R} t_{iI't}\right] + \lambda_k^N \left[\theta_{A'}^{N} t_{iA't} + \theta_{I'}^{N} t_{iI't}\right] + m_{ik}. \tag{7}$$

Now, as an example, suppose there are two different types of workers p and n of the same level of overall experience (i.e., $t_{pt} = t_{nt} \equiv t_t$) who both work in industry. Suppose worker p spent all previous years employed in academia as a postdoc, whereas worker n has worked

[21] Previous employment could include one's time as a student.

[22] This simple model treats sector-specific task j productivity, λ_k^j, and the rate at which workers accrue task j specific human capital when employed in sector k, θ_k^j, as exogenous. However, some minimal assumptions can be made relating these two rates for sake of clarification. Let $\mathcal{J}$ denote the set of all tasks $\{1, \ldots, J\}$. There may exist some set of tasks $\mathcal{J}_k^- \subset \mathcal{J}$ that are not useful in production in sector k, and so for each $j^- \in \mathcal{J}_k^-$ we have $\lambda_k^{j^-} = 0$. Assume that if $\lambda_k^{j^-} = 0$, then $\theta_k^{j^-} = 0$; that is, if a task j^- is not useful in production in sector k, then workers do not perform task j^- when employed in sector k. Likewise, let $\mathcal{J}_k^+ \subseteq \mathcal{J}$ denote the set of tasks that are useful for production in sector k (i.e., where $\lambda_k^{j^+} > 0$). Assuming that all tasks $j^+ \in \mathcal{J}_k^+$ are performed simultaneously to produce output in sector k at time t, then $\theta_k^{j^-} = 0$ for all $j^- \in \mathcal{J}_k^-$ and $\theta_k^{j^+} > 0$ for all $j^+ \in \mathcal{J}_k^+$.

in industry ever since graduation. Then we have the following:

$$w_{pIt} = \alpha_I + \lambda_I^R \theta_{A'}^R t_t + \lambda_I^N \theta_{A'}^N t_t + m_{pI},$$
$$w_{nIt} = \alpha_I + \lambda_I^R \theta_{I'}^R t_t + \lambda_I^N \theta_{I'}^N t_t + m_{nI},$$

where $m_{ik} = \lambda_k^R H_i^R + \lambda_k^N H_i^N$. Then wage inequality between these workers is either due to differences in endowed task-specific human capital or differences in accrued task-specific human capital caused by $\theta_{A'}^R \neq \theta_{I'}^R$ or $\theta_{A'}^N \neq \theta_{I'}^N$.[23]

Let $\Delta^j \equiv \theta_{A'}^j - \theta_{I'}^j$ and $m_{\Delta I} \equiv m_{pI} - m_{nI}$. Then wages for both types of workers can be written as the following:

$$w_{iIt} = \alpha_I + \lambda_I^R \theta_{I'}^R t_t + \lambda_I^N \theta_{I'}^N t_t + m_{nI} + 1[i = p] * \left\{ \lambda_I^R \Delta^R t_t + \lambda_I^N \Delta^N t_t + m_{\Delta I} \right\} \tag{8}$$

where $1[i = p] = 1$ if worker i is type p and $1[i = p] = 0$ if worker is type n. Equation (8) implies that industry wage differences between postdoc-trained (type p) and nonpostdoc-trained (type n) workers of the same cohort are due to differences in worker-sector match quality $m_{\Delta I}$ — which is governed by differences in endowed ability in each task (i.e., differences in H_i^j) — and between-sector differences in the rate of task j specific human capital accumulated as part of production (Δ^j). In this simplified example, we considered the case where a postdoc-trained doctorate is entering the first year of employment in industry. However, under the assumption that θ_k^j and λ_k^j remain fixed over time for each sector and do not differ by worker type, differences in task-specific human capital, and thus wage inequality, will persist between postdoc-trained and nonpostdoc-trained workers in industry. Note that the magnitude and direction of the difference is an empirical question: if pure research abilities are more valuable than other types of abilities in industry, then postdoc training could potentially lead to biomedical doctorates with postdoc-training earning more than their

[23] A reasonable assumption might be that $\theta_{A'}^R > \theta_{I'}^R$ and $\theta_{A'}^N < \theta_{I'}^N$.

nonpostdoc-trained counterparts.[24] However, it could be the case that nonresearch skills are sufficiently valued in industry that nonpostdoc-trained workers in industry tend to earn more.[25] Lastly, differences in task-specific human capital accrual between postdoc-trained and nonpostdoc-trained biomedical doctorates working in industry could be perfectly offset by differences in the productivity of each task, resulting in no wage inequality.

4 Empirical Strategy

In addition to the sample restrictions discussed in Section 2, we limit our analytical sample to biomedical doctorates that are observed at least once after their first six years post-PhD, and at least once in a job after completing postdoc training (if applicable), to ensure the consistency of sample members across regression specifications, some of which, by design, exclude observations corresponding to the first six years post-PhD as well as any years when a doctorate is employed as a postdoc.[26] Table 1 reports summary statistics for the analytical sample broken down by postdoc-trained status and employment sector (academia and industry).[27] As in Appendix B.2, we find that postdoc-trained biomedical doctorates are more likely to be foreign-born and to be temporary residents compared to nonpostdoc-trained biomedical doctorates. They also tend to be younger at time of PhD graduation and less likely to be married and to have children living at home. Additionally, postdoc-trained biomedical doctorates are more likely to have been funded by research assistantships as graduate students and to have finished the PhD more quickly. Due to these differences between postdoc-trained and nonpostdoc-trained biomedical doctorates, we include the characteristics in Table 1 among the controls used in the regression analyses.

[24] This assumes that postdoc training is primarily focused on pure research.

[25] Allowing for more than 2 tasks, it could be that the type of research conducted in academia is qualitatively different from that in industry.

[26] This ensures that differences between results discussed in Section 5 are not due to changes in the underlying sample members.

[27] Summary statistics for the full sample and "Gov't/Nonprofit" sector are reported in Table A.2. A given doctorate who switches employment sector during their career will appear in multiple employment sector subsamples.

Our baseline empirical model for examining the effect of postdoc training on salary is given by the following person-year level Mincer equation:

$$\log(earn_{ifct}) = \boldsymbol{X_i}\boldsymbol{\beta} + \theta Post_i + \boldsymbol{Exp_{it}}\boldsymbol{\lambda} + \boldsymbol{\gamma_f} + \boldsymbol{\gamma_c} + \boldsymbol{\gamma_t} + \varepsilon_{ifct}, \tag{9}$$

where $earn_{ifct}$ is the year t inflation-adjusted annualized salary of doctorate i who graduated with a PhD in field f in year c, $\boldsymbol{X_i}$ is a vector of pre-determined individual-level controls, $Post_i$ is an indicator variable for if doctorate i is postdoc-trained, $\boldsymbol{Exp_{it}}$ is a vector containing a quartic polynomial in experience, $\boldsymbol{\gamma_f}$ are field fixed effects, $\boldsymbol{\gamma_c}$ are PhD graduation year/cohort fixed effects, $\boldsymbol{\gamma_t}$ are normalized year fixed effects, and ε_{ifct} is an idiosyncratic error term.[28] We cluster standard errors at the person-level as each biomedical doctorate may appear more than once in the estimation sample and the regressor of interest, $Post_i$, is fixed for each doctorate. For each person-year observation, we use the sample weight associated with the SDR wave in which the observation appears and include the controls listed in Table A.1 which includes race, sex, age at PhD, number of years spent in graduate school, source of PhD study financial support, whether completed professional degree in conjunction with PhD, marital status at time of graduation, whether had child at home at time of graduation, foreign-born status, and whether the individual was a temporary resident.[29]

Our preferred specification augments (9) with field-by-cohort fixed effects ($\boldsymbol{\gamma_{fc}}$) to control for field-cohort specific shocks that could influence both a doctorate's decision to pursue a postdoc and future career outcomes.[30] Our preferred specification also includes PhD

[28]Salary is adjusted using the CPI-U with base years 1982-84. We follow Murphy and Welch (1990) and Lemieux (2006) by including a quartic polynomial in experience. To address the issue of collinearity between cohort fixed effects, year fixed effects, and experience, we normalize year fixed effects as in equation 2.95 of Deaton (1997) which, as discussed in Aguiar and Hurst (2013) and Lagakos et al. (2018), results in salary growth over time being attributed to experience and cohort effects, and restricts year fixed effects to capture only cyclical fluctuations in salary.

[29]See Table A.3 for results from a person-level regression of the postdoc indicator on the time-invariant controls.

[30]Such shocks include the number of PhDs and postdocs in one's own field of study, the level of NIH funding allocated to one's field, and field-specific research agendas and breakthroughs (e.g., the Human Genome Project, the use of MRI and fMRI), as well as technological and methodological progress (e.g., advances in semiconductor technology leading to both increases in computational power and decreases in cost, emergence of AI and machine learning methods in biomedical research) that open up both new avenues

institution (i.e., *alma mater*) fixed effects ($\boldsymbol{\gamma_s}$) to capture the impact of PhD institution — and any unobserved characteristics of the doctorate that led to his or her acceptance into that PhD institution and that may be correlated with the decision to do a postdoc — on future career outcomes. In addition to the full sample, we conduct regression analyses on three subsamples based on employment sector — academia, industry, or government/nonprofit — since the return to doing a postdoc likely varies by employment sector.

We first estimate the impact of postdoc training on salary using all observations in the estimation sample, including those corresponding to years when a doctorate is employed as a postdoc. For these regressions, we follow Kahn and Ginther (2017) in associating each doctorate with the sector in which they employed at 10 years after graduation.[31] As it is well-known that postdocs get paid less than nonpostdocs throughout the duration of their postdoc employment, we subsequently consider a separate analysis where, for postdoc-trained doctorates, we include only observations for years after their postdoc training has ended.[32] This allows us to explicitly estimate the effect of postdoc training on *future* salary in the absence of its effect on current salary and also allows us to group person-year observations by the employment sector associated with each observation, rather than with the employment sector of the doctorate at a single point in time. In this way we generate an estimate of the impact of postdoc training on *after-postdoc* salary that is less susceptible to possible bias caused by doctorates switching between employment sectors over the course of their career.

Of course, since postdoc-trained status is clearly endogenous, this estimated impact of postdoc training on future salary is unlikely to represent the true causal effect of postdoc

for research and new economic opportunities. For example, see the large increases in the number of NIH-supported PhD recipients in neuroscience and neurobiology since the 1990s: `https://report.nih.gov/nihdatabook/report/267`.

[31] Since the SDR is biennial, a doctorate may not be observed in the data at exactly 10 years post-PhD. Therefore, for those who are not in the data 10 years post-PhD, we impute their employment sector using 11 years, 12 years, and then 9 years post-PhD. We also restrict that the imputed employment sector not come from an observation when the person is employed as a postdoc since we are interested in the after-postdoc employment sector.

[32] Given that the average postdoc duration is between five and six years in biomedical science (see Figure A.2), for these specifications, we drop observations corresponding to a doctorate's first six years post-PhD regardless of postdoc status, in addition to dropping any other observations from years when a doctorate is employed as a postdoc, so that postdoc and nonpostdoc observations are comparable.

training: the choice to pursue postdoc training is likely correlated with unobserved factors such as skill endowments not fully captured by the observed controls. Therefore, we estimate Oster (2019) bias-adjusted treatment effects to test the sensitivity of our results to plausible selection on unobservable ability at time of PhD graduation. Oster's (2019) bias-adjusted treatment effect estimator is motivated by the following data-generating process:

$$Y = \beta X + \Psi\omega^0 + W_2 + \varepsilon,$$

where Y is the outcome of interest, X is a scalar treatment variable, ω^0 is a vector of observed controls, and W_2 and ε are unobserved.[33] Letting $W_1 \equiv \Psi\omega^0$, a proportional selection relationship can be defined as $\delta\frac{\sigma_{1X}}{\sigma_1^2} = \frac{\sigma_{2X}}{\sigma_2^2}$, where $\sigma_{iX} \equiv \text{cov}(W_i, X)$ and $\sigma_i^2 \equiv \text{var}(W_i)$ for $i \in \{1, 2\}$, and where δ measures the level of selection on unobservables relative to observables. Let the coefficient and the R^2 obtained from a regression of Y on X ("uncontrolled regression") be denoted $\mathring{\beta}$ and $\mathring{R}$, respectively. Let the coefficient and the R^2 obtained from a regression of Y on X and ω^0 ("controlled regression") be denoted $\tilde{\beta}$ and $\tilde{R}$, respectively. Lastly, let the R^2 obtained from a hypothetical regression of Y on X, ω^0, and W_2 ("fully-specified regression") be denoted as R_{max}. Then, under some additional assumptions, Oster (2019) shows that a consistent bias-adjusted treatment effect (β^*) can be approximated by the following:

$$\beta^* \approx \tilde{\beta} - \delta\left[\mathring{\beta} - \tilde{\beta}\right]\frac{R_{max} - \tilde{R}}{\tilde{R} - \mathring{R}}.$$

Oster (2019) subsequently develops a consistent bias-adjusted treatment effect estimator that relaxes the additional restrictions used to derive the above approximation, and we use this more robust estimator to measure the sensitivity of our results to selection on unobservables.[34]

[33] A key assumption in what follows is that W_2 is orthogonal to W_1; therefore, W_2 should be viewed as the *residualized portion* of the unobservables after a hypothetical regression of the unobservables on ω^0. See Appendix A.1 of Oster (2019) for a discussion of this assumption.

[34] This method is implemented using the user-created Stata command *psacalc* accessible via Emily Oster's website.

Assuming that postdoc employment and industry jobs differ in the types and intensities of the tasks performed on-the-job, a model of task-specific human capital as in Section 3 implies that biomedical doctorates forgoing postdoc training and instead heading straight to industry after graduation will accumulate more industry-relevant task-specific human capital by the time a postdoc-trained biomedical doctorate from the same PhD cohort first enters industry. Because of this, we expect postdoc-trained biomedical doctorates to earn less in industry than their nonpostdoc-trained counterparts holding years since PhD graduation constant. We also expect that the salary gap would narrow if we were able hold the number of years of industry employment constant. Given data limitations, including the biennial nature of the SDR, we are not able to accurately count the number of years each doctorate spends in each employment sector. However, we are able to proxy for such an approach by considering specifications where we redefine experience as the number of years of nonpostdoc employment, rather than the number of years since graduation. Holding this measure of experience constant is akin to comparing the salaries of postdoc-trained and nonpostdoc-trained biomedical doctorates at a time when both should have similar levels of industry-relevant human capital and essentially treats postdoc training as schooling rather than labor market experience.[35]

If differences in task-specific human capital are a main driver of the industry postdoc salary penalty, then we would expect this penalty to be greatest for those who spend the most years employed as postdocs and thus defer on-the-job task-specific human capital acquisition in industry the longest. To see if this is indeed the case, we estimate specifications where we partition $POST_i$ into three separate indicator variables based on the number of years that we observe a doctorate employed as a postdoc: an indicator for if a doctorate did a postdoc 1) no longer than three years, 2) for greater than three years but less than six years, and 3) exceeding six years.

We also analyze the impact of postdoc training on the ability of biomedical doctorates to

[35]In regressions using this definition of experience, we do not remove observations corresponding to the first six years post-PhD for nonpostdoc-trained biomedical doctorates.

obtain research jobs in academia and industry. Our empirical model for examining the effect of postdoc training on the likelihood of obtaining research jobs is given by the following person-level linear probability model (LPM) specification:

$$job_{ifcs} = \boldsymbol{X_i}\boldsymbol{\beta} + \theta Post_i + \boldsymbol{\gamma_{fc}} + \boldsymbol{\gamma_s} + \varepsilon_{ifcs}, \tag{10}$$

where job_i is an indicator variable for if doctorate i ever obtains a given research job and all other variables are defined as before. We consider four different indicator variables: The first is for whether a doctorate ever finds a nonpostdoc research position in academia ("academic"), the second is for whether a doctorate ever lands a tenure-track research job in academia ("tenure-track"), the third is for whether an individual obtains tenure in an academic research position ("tenured") conditional on having obtained a tenure-track research position, and the fourth is an indicator variable for if a doctorate ever obtains a research position in industry conditional on ever working in industry ("industry").[36] The analytical sample members for these regressions are the same as those in the salary regressions and robust standard errors are computed allowing for clustering at the field-by-cohort level.

5 Main Results

Table 2 reports regression results where an indicator variable for if a biomedical doctorate ever received postdoc training serves as the main variable of interest and where, as in Kahn and Ginther (2017), we include all person-year observations in the analytical sample including observations corresponding to years when a biomedical doctorate is employed as a postdoc. We focus attention to specification (2) as it is the more general specification. The estimates in Panel A suggest that, on average, postdoc training results in a 13.8% decrease in annual salary. However, the returns to doing a postdoc are likely to vary by sector of employment.

[36] "Research job" includes jobs where the primary activity is reported as one of the following: basic research, applied research, development, or design. We also include regressions where we do not restrict the job to being a research position.

Therefore, we break the observations into three groups based on the employment sector of the biomedical doctorate at 10 years post-PhD. The results in Panel B suggest that postdoc-trained biomedical doctorates in academia earn about 6.0% less than nonpostdoc-trained biomedical doctorates. In contrast, a postdoc-trained biomedical doctorate who works in industry faces a 21.3% postdoc salary penalty, as shown in Panel C. Panel D suggests that postdocs may face a penalty when entering government or nonprofit organizations, but this penalty is not statistically significant in the preferred specification. The difference in the magnitude of the estimates between the industry and academic employment sectors is likely driven in part by the higher starting salaries in industry as evidenced in Figure 1.

Since the impact of postdoc training on salary likely varies over a person's career, we consider an augmented version of specification (2) that allows for interactions between the indicator variable for postdoc training and the quartic polynomial in years since PhD graduation. Figure 2 plots the average predicted salary profile for biomedical doctorates with and without postdoc training for each of the first 20 years post-PhD as implied by the augmented version of specification (2) for academia and industry.[37] As we can see, postdoc training leads to lower salary early in a biomedical doctorate's career regardless of employment sector at 10 years post-PhD. For postdocs that find after-postdoc employment in academia, we find an initial postdoc salary gap that dissipates over time. In contrast, postdoc-trained biomedical doctorates in industry suffer a greater gap in salary that persists longer into their career. These results suggest that biomedical postdocs not only experience lower salary while employed as postdocs, but also suffer an after-postdoc salary penalty if entering industry.

To explicitly test whether postdoc training impacts after-postdoc salary, we estimate the effect of postdoc training on *future* salary in the absence of its effect on current salary

[37]The plots are generated by the following process: For each doctorate in the given employment sector sample, we generate two predictions of log(salary) in each year since PhD. The first prediction gives the log(salary) predicted if the doctorate is assumed to have done a postdoc and the second prediction gives the log(salary) predicted if the doctorate is assumed to have not done a postdoc. Then, we average the predicted log(salary) across individuals in the given employment sector in each year since PhD and apply the exponential function to translate log(salary) into salary. We then plot these average predicted salary profiles in Figure 2.

by keeping only those person-year observations corresponding to years after a biomedical doctorate's completion of any and all postdoc positions.[38] Table 3 reports the regression results for this analysis where an indicator variable for if a biomedical doctorate ever received postdoc training serves as the main variable of interest. We first focus attention to specification (2) where we define experience as years since PhD graduation and where we include field-by-cohort fixed effects as well as PhD university fixed effects.[39] The result for the full estimation sample suggests that, on average, postdoc training results in a 11.7% decrease in annual salary following the completion of one's postdoc position. As before, we break the observations into three groups based on the employment sector of the biomedical doctorate, but we assign each person-year observation to a subsample based on the actual sector of employment for the doctorate in the given year, rather than the employment sector of the doctorate 10 years post-PhD.[40] We find that if a postdoc lands a position in academia, then he or she does not face a postdoc penalty; in contrast, we find that postdocs working in industry face a 15.8% penalty on after-postdoc salary, and that postdocs in government/nonprofits face a 10.6% salary penalty.

We next consider an augmented version of specification (2) that includes interactions between the postdoc indicator and the quartic polynomial in years since PhD graduation and plot the resulting average predicted salary profiles generated from the fitted values of such a regression in Figure 3. As shown in Figure 3, postdoc training is associated with a persistent salary penalty in industry, whereas in academia postdoc training appears to have a slight negative impact on salary early in a doctorate's after-postdoc career, but enhances salary growth such that the salary of postdoc-trained biomedical doctorates catches up and then exceeds that of nonpostdoc-trained doctorates after about 15 years post-PhD.

[38] For specifications (1) and (2) where experience is defined as the number of years since PhD graduation, we also drop observations corresponding to a person's first six years post-PhD so that postdoc and nonpostdoc observations are comparable.

[39] Specifications (1) and (3) are included for comparison purposes to demonstrate the importance of controlling for field-cohort fixed effects and PhD university fixed effects.

[40] See Table A.4 for results where we use the employment sector at 10 years post-PhD for subsampling. The results remain similar to what we find in Table 3 except for the government and nonprofit subsample in specifications (2) and (4) where we control for field-cohort fixed effects.

These results are consistent with the view that postdoc training is geared towards building academic-specific human capital that increases one's chances of obtaining a higher-paying research-based academic job.[41]

If postdoc-trained biomedical doctorates have lower ability at the time of PhD completion than those who forgo postdoc employment, then the postdoc salary penalty in industry reported in column (2) of Table 3 could potentially be explained by selection on unobserved ability at time of graduation. We find this unlikely for two reasons: First, Sauermann and Roach (2016) find that higher-ability biomedical doctorates plan on pursuing postdoc training, which would point to our estimates of a postdoc penalty being too conservative rather than too extreme.[42] Second, we include controls that are likely correlated with ability at time of graduation; these include field-by-cohort fixed effects, PhD university fixed effects, the education level of each biomedical doctorates' mother and father, length of time in a graduate program, graduate program funding source, and various background characteristics that are likely related to ability.[43]

Nevertheless, we test whether residual variation in unobserved ability at time of graduation might explain the postdoc salary penalty in industry by estimating bias-adjusted treatment effects as formulated in Oster (2019) and report the results of this robustness check in Table 8. We find that the inclusion of controls, which are plausibly correlated with

[41]The negative impact early in a postdoc-trained biomedical doctorate's career may be due to nonpostdoc-trained doctorates of the same cohort being promoted to a higher academic rank sooner than those who enter a tenure-track position after spending multiple years as a postdoc. Agarwal and Ohyama (2013) find a similar criss-crossing pattern when comparing the salary of those in academia primarily focused on basic science versus applied science, with those in basic science starting with lower salary but having a steeper salary profile. In Figure B.7, we show that a greater share of postdoc-trained biomedical doctorates are engaged in basic research as opposed to those in academia without postdoc training. However, Agarwal and Ohyama (2013) include observations corresponding to years when doctorates are employed as postdocs, as well as including doctorates outside of biomedical science, and so their results are not directly comparable to ours.

[42]Ability is proxied by four measures in Sauermann and Roach (2016): 1) number of peer-reviewed publications, 2) fellowships from a federal agency, 3) their PhD program's National Research Council (NRC) ranking, and 4) respondent's assessment of their own research ability relative to peers.

[43]Field-by-cohort fixed effects will be correlated with ability if individuals sort into different biomedical fields based on ability. PhD university fixed effects will be correlated with ability insofar as universities admit students to biomedical PhD programs based on individual ability (e.g., as measured by application materials including GRE scores and GPA) and insofar as different universities have different impacts on the human capital accumulation of PhD students. Parent's education level may proxy for socioeconomic background and possibly inherited traits impacting educational performance.

ability, pushes the estimated impact of postdoc training on future salary in a negative direction for all subsamples, which is consistent with postdoc-trained biomedical doctorates having higher ability than their nonpostdoc-trained counterparts. While we are not able to pinpoint the causal impact of postdoc training in the absence of a valid instrument for postdoc attainment, under the plausible assumption that selection on unobservables acts in the same direction as selection on observables, we can bound the value for the causal impact by using the Oster (2019) method for estimating bias-adjusted treatment effects. To do so, we must select an upper-bound for the level of selection on unobservables relative to selection on observables (δ) and the R^2 that we would expect from a fully-specified model that we would be able to estimate if the unobservables were instead observable (R_{max}). We follow Altonji, Elder, and Taber (2005) and Oster (2019) in treating $\delta = 1$ as an upper-bound for the level of selection on unobservables relative to observables.[44] Oster (2019) suggests that researchers arguing for the stability of their results consistent with that of randomized treatment should consider an upper bound value of $1.3\tilde{R}^2$ for R_{max}, where $\tilde{R}^2$ is the R^2 obtained from the controlled regression. Thus, we use this R_{max} and $\delta = 1$ to calculate an upper-bound value for the impact of postdoc training on after-postdoc salary in each employment sector, which we report as $\hat{\theta}(\delta = 1, R_{max})$ in Table 8.

We find that each point estimate is negative and of greater magnitude compared to the estimate in the corresponding controlled regression, suggesting that, under the plausible assumption that selection on unobservables runs in the same direction as selection on observables, the magnitude of each estimate in column (2) of Table 3 is a lower-bound for the causal impact of postdoc training on after-postdoc salary, while each estimate reported as $\hat{\theta}(\delta = 1, R_{max})$ represents an upper-bound.[45] Altogether, these results suggest that abil-

[44] As argued in Oster (2019), δ represents the relative degree of selection on the *residualized portion* of the unobservables (i.e., the variation in the unobservables unrelated to variation in the observables).

[45] The calculated upper-bounds all lie outside the 95% confidence interval of the corresponding estimate in column (2) of Table 3, indicating that correcting for selection on unobservables is potentially important. In Table A.5, we report a set of bias-adjusted estimates of the effect of postdoc training on after-postdoc salary for each sector assuming different values of selection on unobservables relative to observables (δ) and R_{max}. While we view $R_{max} = 1.3\tilde{R}^2$ as a sensible upper-bound for R_{max}, we also report a loose upper-bound for R_{max} by obtaining the R^2 from a regression of log(salary) on person fixed effects and a quartic

ity bias is unlikely to explain the existence of a postdoc penalty in industry, and that the true salary penalty in industry caused by postdoc training is somewhere between 15.8% and 26.2%, depending on the level of selection on unobservables and the degree to which inclusion of the unobservables as controls would increase the R^2 of the model.

The estimates reported in columns (1) and (2) of Table 3 are the result of specifications where postdoctoral training is treated as contributing to general labor market experience: for example, biomedical doctorates who spend six years in postdoc training and first enter industry at seven years post-PhD are treated as having the same level of labor market experience as a biomedical doctorate of the same cohort who has worked in industry ever since graduation. Since postdoc training and on-the-job training in industry likely emphasize different sets of skills, we would expect within-cohort differences in task-specific human capital between ex-postdocs and nonpostdocs working in industry conditional on years since PhD, resulting in salary differences. If postdoc training is instead treated as a type of schooling and experience is defined as the number of years in post-PhD nonpostdoc employment, we would not expect such differences. Therefore, we estimate specifications (3) and (4) which are identical to specifications (1) and (2), respectively, except that experience is defined as the number of years in post-PhD nonpostdoc employment. Focusing on specification (4), we find that the postdoc penalty on salary in industry is no longer statistically significant when experience is defined in this way, and we also find that postdoc training is associated

polynomial in experience. We view this as a loose upper-bound for the true R_{max} since person fixed effects will not only absorb the effects of time-invariant observables and unobservables at the time of graduation, but will also absorb the effect of observables and unobservables that *look* time-invariant; for example, a doctorate might work at the same employer in every year that we observe their salary, and so person fixed effects for this individual will, in this case, also absorb the effects of the firm where they work. Altonji, Arcidiacono, and Maurel (2016) note that in the context of evaluating the impact of college field choice on future earnings, "much of the variance in earnings at a point in time is due to measurement error or permanent and transitory shocks that occur after college decisions have been made" and thus are not a source of selection bias. The same argument can be made for the postdoc decision. In a fully-specified model used to estimate the overall impact of postdoc training on salary, we would not want to include employer-based characteristics as controls since postdoc training likely impacts salary in part through altering the likelihood that a person will be hired by a specific employer, and so these are "bad controls" in the language of Angrist and Pischke (2008). Nevertheless, examining how controlling for firm characteristics impacts the estimated postdoc penalty may be useful for exploring the mechanisms through which the postdoc penalty operates, and is akin to our subsample analyses where we implicitly control for the differential sorting of postdoc-trained and nonpostdoc-trained biomedical doctorates across employment sectors.

with a statistically significant 9.83% increase in salary in academia. Next, we consider an augmented version of specification (4) that includes interactions between the postdoc indicator and the quartic polynomial in years of post-PhD nonpostdoc employment. As shown in Figure 4, postdoc training is associated with a persistent increase in salary for academic jobs, whereas postdoc training does not significantly impact salary in industry. These findings are consistent with the view that postdoc training in biomedical science is specialized academic training, and so the postdoc penalty in industry that we observe in column (2) of Table 3 is driven by differences in the accumulation of industry-relevant human capital between postdoc-trained and nonpostdoc-trained biomedical doctorates early in their career. These results also suggest that, for biomedical doctorates working in academia, postdoc training improves one's chances of obtaining a higher-paying research-based job.

To test the extent to which postdoc training enhances a biomedical doctorate's chances of working in research-focused jobs, we estimate the impact of postdoc training on ever obtaining a nonpostdoc academic research job, a tenure-track research position, ultimately attaining tenure in a research position, and obtaining a research position in industry conditional on ever working in industry. Panel B of Table 4 reports the results using the LPM specification given by (10).[46] To measure the impact of doing a postdoc on ever obtaining a (nonpostdoc) academic research job, we regress an indicator variable for if a biomedical doctorate ever works in an after-postdoc research job in academia on an indicator variable for if the individual has postdoc training. We find that doing a postdoc increases the likelihood of working in an academic research position by about 26.5 percentage points.[47] Next, we find that postdoc training increases the chances of landing a tenure-track position by about 21.5 percentage points. Lastly, among those that ever take a tenure-track job and whom we observe after they are up for their tenure decision, we estimate the impact postdoc training

[46]For comparison purposes, Panel A reports the results when we omit restricting the position to being one where research is the primary work activity.

[47]In results not shown, we find that postdoc training is associated with a 24.2 percentage-point increase in the likelihood of working in any research-focused job (i.e., regardless of employment sector).

on obtaining tenure.[48] We find that postdoc training does not significantly impact the ability of tenure-track researchers to obtain tenure. Lastly, we estimate the impact of postdoc training on the ability to ever obtain a research position in industry among doctorates ever working in industry. The last column in Panel B of Table 4 shows that postdoc training raises the probability of obtaining a research position in industry by about 12.3 percentage points.

As with the impact of postdoc training on salary, unobservable ability at the time of graduation could potentially explain the impact of postdoc training on the ability of biomedical doctorates to obtain different types of research-focused jobs. Therefore, we test the robustness of our research job regression results reported in Panel B of Table 4 to selection on unobservables using the Oster's (2019) method as before and report the results in Table 9. We find that the results in Panel B of Table 4 represent upper-bound estimates of the true impact of postdoc training on the likelihood of obtaining tenure-track and industry research jobs, whereas the bias-adjusted treatment effects represent lower-bounds. This finding, in conjunction with the direction of bias detected in the salary regressions, is consistent with postdoc-trained biomedical doctorates having greater ability at the time of graduation compared to their nonpostdoc-trained counterparts, assuming that high-ability doctorates are more likely to obtain tenure-track and industry research positions. On the other hand, we find that correcting for selection on unobervables increases the positive effect of postdoc training on the chances that a biomedical doctorate works in any academic research job after-postdoc. This may indicate that lower ability doctorates sort into nontenure-track research positions in academia, such as staff scientist positions. However, we find that, in all cases, the bias-adjusted treatment effect lies within one standard error of the estimates reported in Table 4, indicating that the results are not especially sensitive to selection on unobservables.[49]

[48] This sample includes individuals who report being on the tenure track at some point and then later report either 1) being in a tenured position or 2) not in a tenured position and no longer on the tenure track.

[49] We use the standard errors reported in Table 4. The results for tenured positions are quite sensitive to selection on unobservables — this makes sense given the sensitivity of the results to selection on observables,

The positive association between postdoc training and the likelihood of obtaining a research-focused job in industry suggests that postdoc training might enhance one's research skills. If this is the case, we would expect the industry postdoc salary penalty to be smaller among biomedical doctorates employed in research-focused positions. Therefore, we estimate subsector salary regressions for "Industry Research" and "Industry Nonresearch" and report results in Table 5. These results suggest that the industry postdoc salary penalty is indeed smaller for those in industry research jobs — the estimated magnitude is just over half that for industry nonresearch jobs, and only marginally significant. For both subsectors, we find no statistically significant postdoc salary penalty when experience is defined as years of post-PhD nonpostdoc employment.

We also estimate subsector regressions for academia, breaking academia down into three subsectors: "Academic Tenure-Track (TT) Research", "Academic Non-Tenure-Track (TT) Research", and "Academic Nonresearch." When experience is defined as years since PhD graduation, postdoc-trained biomedical doctorates appear to earn less in TT research positions, no differently in nonresearch positions, and earn more than their nonpostdoc-trained counterparts in non-TT research positions. When redefining experiene, we find no substantial differences in salary between ex-postdocs and nonpostdocs in TT research and nonresearch positions, but find a substantial postdoc *premium* in non-TT research positions. This suggests that previous postdoc training increases the productivity of non-TT researchers, which could be due to similarities in the set of tasks emphasized in both types of jobs.[50]

The results reported in Table 3 estimate the impact of postdoc training on future salary, regardless of the length of postdoc training. If differences in salary between ex-postdocs and nonpostdocs in industry are driven by differences in task-specific human capital, we would expect ex-postdocs who spent the longest time in postdoc training — and therefore deferred on-the-job training in industry for the longest — to suffer the largest salary penalties. To

paired with the fact that inclusion of the observable controls increases the R^2 drastically relative to the uncontrolled regression.

[50]See Table Table A.6 for subsector regressions where, as in Table 2, we include observations for years when doctorates are employed as postdocs and employment sector is defined as that at 10 years post-PhD.

test this, we repeat the analysis in Table 3 after replacing the single indicator variable for if a biomedical doctorate ever did a postdoc with three indicator variables: an indicator for if a doctorate did a postdoc 1) no longer than three years, 2) for greater than three years but less than six years, and 3) exceeding six years. Table 6 reports the results. We first focus attention to specification (2) where experience is defined as years since PhD graduation. The results suggest that postdocs finding a job in academia do not suffer a salary penalty regardless of how long they are employed as a postdoc. However, biomedical doctorates who spend any number of years employed as a postdoc experience a salary penalty in excess of 10% in industry, with those who spend the most time working as a postdoc suffering the largest penalty. In specification (4) we redefine experience as the number of years of nonpostdoc employment and find that the postdoc penalty in industry is no longer statistically significant for postdocs of any length. We also detect increases in after-postdoc salary for biomedical doctorates that spend greater than three years in postdoc positions and who find employment in academia; those with the longest postdocs tend to earn more, possibly due to postdoc employment serving as a holding position as one waits for a tenure-track research position in academia, which are typically higher-paying than other entry-level positions in academia.[51]

To test whether the chances of obtaining a research job in academia, including a tenure-track research position, are increasing in the length of postdoc training, we repeat the analysis in Table 4 after replacing the single indicator variable for if a biomedical doctorate ever did a postdoc with the three indicator variables based on postdoc length. Panel B of Table 7 shows that biomedical doctorates employed in postdoc positions of any length have greater chances than nonpostdocs in obtaining academic research and tenure-track research positions, with those with postdoc lengths exceeding three years having the greatest chances on landing these positions. Additionally, biomedical doctorates with postdoc lengths greater than three years are also more likely to obtain a research position in industry than those without any postdoc experience. The likelihood that a tenure-track researcher obtains tenure does not

[51] Andalib, Ghaffarzadegan, and Larson (2018) model postdoc positions using a queuing model.

appear to be impacted by postdoc length. In general, doing a postdoc longer than three years leads to significantly greater chances of landing an academic research position, a tenure-track research position, and an industry research position.

6 Possible Mechanisms for the Industry Postdoc Salary Penalty

6.1 Compensating Differentials for Research and Other Job Tasks

Autor and Handel (2013) and Deming and Kahn (2018) find that job task requirements are predictive of worker wages even when controlling for education and occupation, and so it could be that industry salary differences between postdoc-trained and nonpostdoc-trained biomedical doctorates arise from differences in the types of job tasks performed as part of current employment. Previous research finds evidence that biomedical doctorates are willing to trade-off salary for the opportunity to participate in research: Stern (2004) finds that postdoctoral biologists pay a negative compensating differential to participate in science after their postdoc and Sauermann and Roach (2014) finds that the PhD candidates most likely to pursue jobs in industrial R&D differ in the price that they are willing to pay to be allowed to publish. Table 4 shows that postdoc training enhances a biomedical doctorate's ability to obtain a research position in industry, and so one may wonder whether the industry postdoc salary penalty is explained by scientists paying to do science, especially since it is plausible that postdocs are among those most willing to sacrifice pay for the ability to publish.

However, these previous studies also provide rationale casting doubt on this mechanism as driving our results. First, Stern (2004) notes that his finding a negative compensating differential to participate in science depends critically on the inclusion of individual fixed effects made possible by the structure of his survey data which includes the observation of

multiple job offers for each postdoc at a given point in time. Second, Sauermann and Roach (2014) note that the scientists who report being willing to pay the highest price to be able to publish in industry are scientists of perceived higher ability and from top-tier institutions, and so tend to be more expensive to hire even if publishing is allowed. Therefore, it seems unlikely that a negative compensating differential for science would be detected in cross-sectional data that does not explicitly ask respondents how much they are willing to pay to do science and does not observe multiple job offers for each doctorate at a given point in time.

Nevertheless, we explore the extent to which the postdoc penalty in industry can be explained by a negative compensating differential for research by adding two indicator variables for the reported primary work activity of industry-employed biomedical PhDs — one for if the job is primarily research-focused and a second for if the job is primarily managerial/administrative — as controls to the regression specification used in column (2) of Table 3.[52] While the ability to conduct R&D in industry is not the same as the ability to publish, these two measures ought to be correlated and so, while imperfect, we believe this exercise is informative as a check on the robustness of our results to a compensating differential to participate in science. The results are reported in column (2′) of Table 10. Comparing the results in column (2′) to those in column (2) — which is a copy of column (2) in Table 3 — we see that the addition of controls for work activity does not diminish, but rather enhances, the estimated postdoc penalty in industry. So while individuals may be likely to forgo a job offer with greater salary potential in favor of a job with a greater orientation towards research, this possible negative compensating differential does not appear to be driving the industry postdoc salary penalty reported in column (2) of Table 3.

However, industry-employed ex-postdocs might differ in terms of other job tasks that they perform on-the-job as part of current employment, or it might be that the type of research (i.e., basic, applied, development, or design) matters when trying to explain the industry

[52] VanderWeele (2016) describes different mediation analysis methods and the assumptions required for a causal interpretation. As these assumptions are strong, we view our mediation analysis exercise as suggestive.

postdoc salary penalty. The SDR asks respondents which work activities take up at least 10% of their work time in their primary job, as well as which work activities constitute the primary and secondary jobs tasks.[53] Table 11 reports estimates of the industry postdoc salary penalty when controlling for alternative sets of indicator variables reporting whether or not a given task is performed 1) as the primary job task, 2) as the primary or secondary job task, or 3) for at least 10% of work time.[54] As we can see, inclusion of mediating controls for current job tasks increases the magnitude of the estimated industry postdoc salary penalty, which suggests that differences in current job tasks do not explain the the postdoc salary penalty in industry.

6.2 Sorting by Occupation or Employer

Another possible explanation is that industry-employed biomedical doctorates with postdoc training tend to sort into different firms or occupations than biomedical doctorates without postdoc training. Barth et al. (2016) find that "much of the 1970s-2010s increase in earnings inequality results from increased dispersion of the earnings among the establishments where individuals work," and so controlling for employer characteristics is likely important. The SDR contains information on occupation, as well as a limited set of employer characteristics including size, location (state/country code), and type. We therefore estimate regressions where worker occupation, employer size, employer location, and employer type are included as controls.[55] Column (2″) of Table 10 reports the results. As we can see, inclusion of these

[53]The list of activities that respondents may select are as follows: 1) Accounting, finance, contracts, 2) Applied research — study directed toward gaining scientific knowledge to meet a recognized need, 3) Basic research — study directed toward gaining scientific knowledge primarily for its own sake, 4) Computer programming — including systems or applications development, 5) Development — using knowledge gained from research for the production of materials, devices, 6) Design — of equipment, processes, structures, models, 7) Human resources — including recruiting, personnel development, training, 8) Managing or supervising people/projects, 9) Production, operations, maintenance — including chip production, operating lab equipment, 10) Quality or productivity management, 11) Sales, purchasing, marketing — including customer service and public relations, 12) Professional services — including health care, counseling, financial services, legal services, 13) Teaching, and 14) Other.

[54]Each of the three sets consists of 14 indicator variables (i.e., one for each task).

[55]Employer types in the industry employment sector include the following: 1) Private-for-profit, 2) Self-employed, not incorporated, 3) Self-employed, incorporated, and 4) Other. See SDR survey questionnaire

controls does not eliminate the industry postdoc salary penalty. While we find no evidence that employer characteristics are a driver of the industry postdoc salary penalty, we cannot rule out this mechanism entirely as employer information in the SDR is limited, and so a linked employer-employee dataset of the doctoral workforce is necessary for a stronger test of this mechanism.[56]

6.3 Seniority Pay

Even if biomedical doctorates in industry with and without postdoc training sort into similar firms and occupations, those who forgo postdoc training to enter industry directly after graduation can build up seniority at the firm where they work, unlike their postdoc counterparts. The existence of a return to employer-specific seniority would mean that when postdoc-trained biomedical doctorates enter a firm, they will tend to be paid less than nonpostdoc-trained colleagues, even if they are otherwise identical in terms of skill.[57] In each SDR wave, respondents are asked if they have the same employer as in the last SDR wave. Using responses to these questions, we construct a variable that measures seniority (i.e., how many years an individual has been at their current employer in a given year). We therefore augment the specification once more by including a quartic polynomial in seniority. Column (2‴) of Table 10 gives the results: we find that including seniority as a control in

for list of occupation codes. We use occupation-by-year fixed effects to control for occupation as this both allows the impact of a given occupation to change over time and also is robust to changes in occupational codes in the SDR that have occurred over time.

[56]Davis et al. (2020) uses American Community Survey (ACS) and Longitudinal Employer-Household Dynamics (LEHD) data to create a new employer-employee linked dataset of the doctoral workforce. Davis et al. (2020) contains a preliminary analysis of the returns to postdoc training for biomedical doctorates and finds that the postdoc salary penalty for nonacademic jobs remains after including both firm fixed effects and occupation fixed effects, although the magnitude of the penalty is reduced relative to specifications not including these controls. Given the differences in the data sources, and thus samples, used in this paper and in Davis et al. (2020), the results are not directly comparable — see Davis et al. (2020) for a fuller discussion. The National Academies of Sciences, Engineering, and Medicine (2018) recommended that the NSF "expeditiously" link the SDR and SED to US Census data and make this data available to researchers in the Census FSRDCs — such a linkage would be beneficial in determining the extent to which postdoc training impacts where biomedical doctorates work, and how controlling for employer changes the estimated effect of postdoc training on salary.

[57]Barth (1997) finds evidence of within-firm seniority pay not explained by firm-specific human capital accumulation using Norwegian microdata.

the regressions does not diminish the estimated postdoc penalty in industry. However, this exercise may be of limited value as the SDR does not have firm identifiers, and it is plausible that returns to seniority differ substantially across firms. Again, a linked employer-employee dataset of the doctoral workforce is necessary for a stronger test of this mechanism.

6.4 Differences in Task-Specific Human Capital Accumulation

If ability bias, a compensating differential for research and other job tasks, occupational and employer sorting, and seniority do not explain the postdoc penalty, then what does? As suggested by the conceptual framework in Section 3, one possible explanation is that human capital is task-specific, and that biomedical PhDs more rapidly accumulate human capital in industry-relevant tasks while on-the-job in industry rather than as postdocs. Previous research finds that tasks are especially important for explaining the life-cylcle earnings of high-skilled and STEM workers: Gathmann and Schönberg (2010) find that the wage effects of switching between two jobs with different associated tasks "are typically strongest for the high-skilled, suggesting that task-specific skills are especially important for this education group." Deming and Noray (2020) find that the relatively-rapid changing of the skill content (or task requirement) of STEM jobs over time is important in explaining the age-earnings profiles of STEM workers. Biomedical doctorates are high-skilled STEM workers, and so these previous findings lend plausibility to task-specific human capital playing an important role in the wage determination of biomedical doctorates.

If the industry postdoc salary penalty is to be explained by differences in accrued task-specific human capital, then we should observe differences in the tasks performed by biomedical doctorates during their postdoc training compared to the tasks performed by nonpostdoc-trained biomedical doctorates working in industry early in their career. In Table 12, we find substantial differences between postdocs and nonpostdocs in the tasks reported as primary work activities at least once in the first six years post-PhD. Around 75% of postdocs report basic research as their primary work activity at least once in their first six years post-PhD,

whereas only around 6% of nonpostdocs do so.[58] Applied research, professional services, development, and management are much more likely to be reported as the primary work activity of nonpostdocs as opposed to postdocs early in their career. Jobs typically require the performance of multiple types of tasks, and so we also consider a broader measure of task-content to characterize the jobs of postdocs and nonpostdocs early in their career. In Table 13, we calculate, for both postdoc-trained and nonpostdoc-trained biomedical doctorates that work in industry at 10 years post-PhD, the percentage of each that, in any of the first six years post-PhD, report working in a job where they spend at least 10% of their time engaged in each given task. As we can see in Table 13, biomedical postdocs are much more likely to be engaged in basic research and slightly more likely to be engaged in applied research during their postdoc employment compared to nonpostdoc-trained biomedical doctorates working in industry during their first six years post-PhD. Meanwhile, postdocs are considerably less likely to be engaged in the other activities which may be considered more industry-relevant, which include development, design, management, and professional services (among other tasks). The stark differences in job tasks performed by biomedical postdocs and those nonpostdoc-trained biomedical doctorates working in industry during the first six years of their career indicate that postdoc training and on-the-job training in industry are distinct training regimens aimed at developing different types of skills.

One empirical implication of a task-specific model of human capital is that, other things equal, a worker who moves to a new job that requires substantially different tasks than their previous job will typically experience a greater salary change than a worker whose previous job had more similar task-requirements (Gathmann and Schönberg, 2010). Therefore, in Table 13 we report, for both postdoc-trained and nonpostdoc-trained biomedical doctorates

[58]For the comparisons in Table 13, we restrict the sample to biomedical doctorates that are employed in industry at 10 years post-PhD, as in Column (2) of Table A.4. For postdocs, we only consider observations in the first six years post-PhD that correspond to years employed as a postdoc; after six years post-PhD, we only consider observations corresponding to years after any and all years employed as a postdoc, and where the doctorate is employed in industry. For nonpostdocs, we only consider observations corresponding to years where the person is employed in industry. We also require that a person shows up in the analytical sample within the first six years post-PhD — this means that doctorates graduating between 1981 and 1986 will be automatically excluded from this analysis since the first wave we include in this study is SDR 1993.

that work in industry at 10 years post-PhD, the percentage of each that, in any year *after* the first six years post-PhD, report working in an industry job where they spend at least 10% of their time engaged in each given task. We then subtract from these calculations the percentage of each that, in any year *within* the first six years post-PhD, report working in a job where they spend at least 10% of their time engaged in each given task, and report this percentage-point difference as the "Task Change." As we can see, postdoc-trained biomedical doctorates in industry experience larger changes in each task relative to nonpostdoc-trained biomedical doctorates (except for computer applications), with these differences often substantially larger than those for nonpostdoc-trained biomedical doctorates in many cases.

Given the differences in tasks performed by postdoc-trained and nonpostdoc-trained biomedical doctorates in industry, we would expect biomedical doctorates with the longest postdocs to experience the largest postdoc penalty on after-postdoc salary in industry. This is what we found in column (2) of Table 6 where biomedical doctorates with postdoc lengths exceeding six years experienced the largest postdoc penalty in industry. Additionally, we would expect the magnitude of the estimated postdoc penalty in industry to decrease when we redefine experience as years of post-PhD employment in nonpostdoc positions rather than as years since PhD graduation; this shifts the focus to comparing the salary of postdoc-trained biomedical doctorates in their first year employed in industry with the pay of non-postdocs in their first year employed in industry, a time where both would be likely to have similar levels of industry-relevant task-specific human capital. We carried out this exercise in column (4) of both Table 3 and Table 6 and found that, in both cases, redefining experience in this way shrinks the magnitude of the estimated postdoc penalty in industry to such an extent that the effect is no longer statistically significant.

A more direct way to test the plausbility of a task-specific human capital explanation of our results is to include measures of the history of tasks performed by biomedical doctorates in previous jobs as mediating controls in industry salary regressions. Given the biennial

nature of the SDR, we are not able to measure the precise task tenure for each doctorate, and so we instead approximate each doctorate's task tenure by calculating the percentage of previous jobs that we observe where the doctorate reports performing the given task and multiplying this value by the number of years since PhD minus one. To improve the accuracy of our task tenure proxies, we limit our sample to those doctorates that we observe at least two times during their first six years post-PhD.[59] Similar to Section 6.1, we calculate three sets of task history variables used to proxy for task-specific human capital accumulation: one set for the number of years where a given work activity was performed as the primary job task, another set for the number of years where a given work activity was performed as the primary or secondary job task, and another set for the number of years where a given task was performed for at least 10% of work time.[60]

Table 14 reports estimates of the industry postdoc salary penalty when controlling for alternative sets of task tenure variables.[61] We see that the magnitude of the industry postdoc salary penalty is substantially reduced when including measures of the history of tasks performed by biomedical doctorates in previous jobs as mediating controls. When controlling for both the history of primary tasks performed and those tasks performed for at least 10% of work time in column (6), we obtain a statistically insignificant estimate of the industry postdoc salary penalty that is roughly one-third the magnitude of the baseline estimate reported in column (1). This lends further plausibility to a task-based explanation of our results where the postdoc salary penalty in industry is caused by differences in the task-specific human capital accumulation of postdoc-trained and nonpostdoc-trained biomedical doctorates.[62]

[59]Since SDR 1993 is the first survey wave of our analytical sample, this restriction implicitly excludes doctorates graduating prior to 1989, as these doctorates would only be observed at most once in their first six years post-PhD in the SDR.

[60]Each set of task history variables is comprised of 14 variables (i.e., one for each task). See Footnote 53 for the list of 14 work activities included in the SDR.

[61]For comparison purposes, Table A.7 reports estimates for the same sample when including controls for current job tasks. Results are qualitatively similar to those in Table 11.

[62]See Table A.8 for coefficient estimates on the primary task history controls included in the specification reported in column (2) of Table 14.

7 Conclusion

In this paper, we introduce a simple task-specific human capital model of wage determination to motivate an analysis of the differences in industry salary between biomedical doctorates with and without previous postdoctoral training. Using a Mincer human capital function that controls for individual-level characteristics, a quartic polynomial in experience, PhD university (i.e., *alma mater*) fixed effects, and field-by-cohort fixed effects, we find that industry-employed biomedical doctorates with postdoc training earn 15.8% less in terms of inflation-adjusted annual salary compared to their nonpostdoc-trained counterparts. We find no evidence that this industry postdoc salary penalty is explained by selection on unobservable ability at time of PhD, differential sorting into firms and occupations, or compensating differentials for conducting research or other tasks as part of current employment.

Instead, we find evidence consistent with a task-specific human capital model of wage determination where differences in salary between postdoc-trained and nonpostdoc-trained biomedical doctorates is the result of differences in the history of tasks performed as part of previous employment. First, we find substantial differences in the tasks emphasized as part postdoc training and industry employment: postdoc training is primarily focused on basic research, with little focus on development, design, management, professional services, and other tasks that are valued in industry employment. Second, inclusion of task history measures as mediating controls substantially reduces the magnitude of the estimated postdoc salary penalty in industry, rendering the estimate statistically insignificant. Third, those that participate in postdoc training the longest appear to suffer the largest postdoc salary penalty in industry, which is expected if differences in salary are largely due to postdocs deferring accrual of industry-relevant task-specific human capital while employed as a postdoc.

A task-specific human capital explanation is also consistent with the views of those within the biomedical community who argue that postdoc training is specialized academic training, and that, in lieu of the growing number of biomedical doctorates working outside academia, initiatives to broaden the types of training and career preparation available to postdocs is

much needed. Towards this end, in 2013, the NIH initiated the Broadening Experiences in Scientific Training (BEST) grant aimed at supporting institutions seeking to provide biomedical doctorates with career development opportunities to facilitate an easier (and quicker) transition from postdoc employment to nonacademic jobs. Programs designed to expose biomedical doctoral students to other career paths before graduation, such as research funding for graduate students that requires participation in a two to three month industrial internship, may better prepare biomedical doctorates for the road ahead.[63] Our results suggest that increasing the exposure of biomedical doctorates to skills valued in industry may be effective at lessening the postdoc salary penalty in industry.

[63] As mentioned in National Academy of Sciences (2014), the National Institute of General Medical Sciences (NIGMS) biotechnology predoctoral training program requires recipients to participate in a two to three month industrial internship.

Figures

Figure 1: Median Salary of Biomedical Doctorates over Career by Prior Postdoc Status

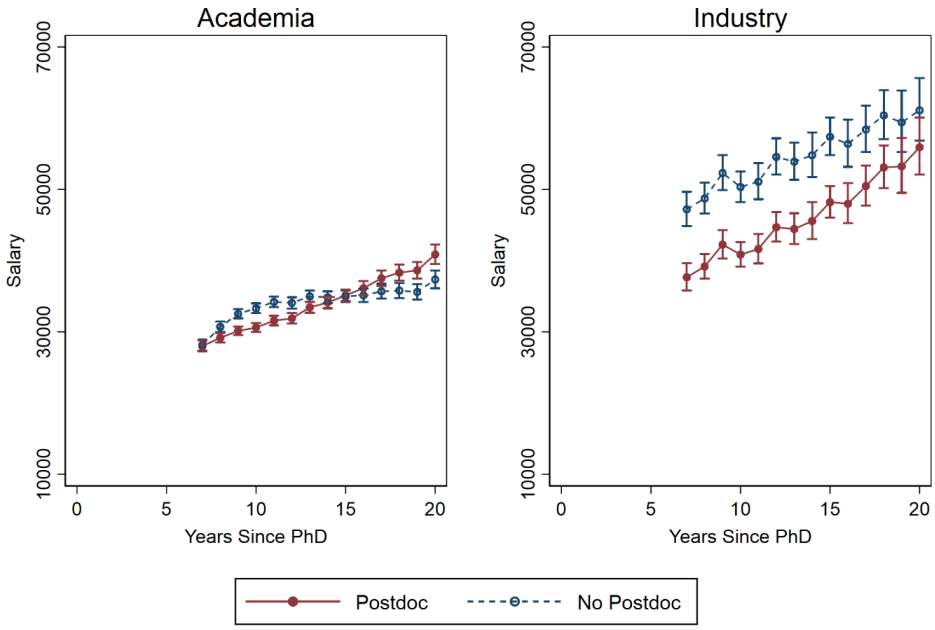

Notes: Figure 1 shows the median salary in each 3-year interval since PhD for biomedical doctorates first appearing in the SDR 1993, 1995, or 1997 waves and who graduated no earlier than 1990. Biomedical doctorates are associated with the employment sector (academia or industry) that they occupy at 10 years post-PhD. Salary adjusted for inflation using the CPI-U with base years 1982-84.

Figure 2: Average Predicted Salary Over Career by Postdoc-Trained Status

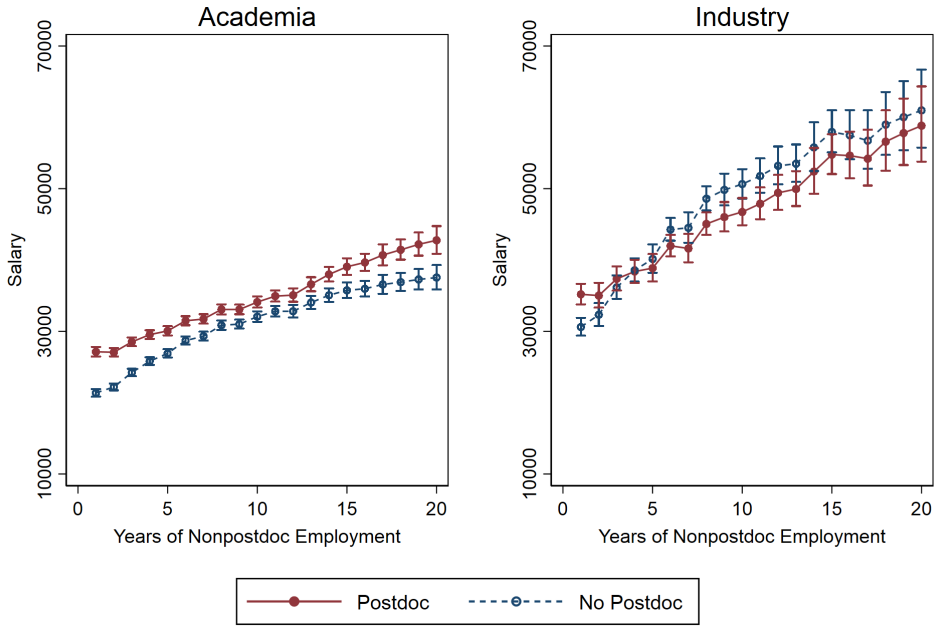

Notes: Figure 2 shows the average of predicted salary profiles for biomedical doctorates with and without postdoc training generated by an augmented version of the regression model found in Column (4) of Table 2 where we allow for interactions between the indicator variable for postdoc training and quartic polynomial in experience. The plots are generated by the following process: For each doctorate in the given employment sector sample, we generate two predictions of log(salary) in each year since PhD. The first prediction gives the log(salary) predicted if the person is assumed to have done a postdoc and the second prediction gives the log(salary) predicted if the person did not do a postdoc. Then, we average the predicted log(salary) across individuals in the given employment sector in each year since PhD and apply the exponential function to translate log(salary) into salary. We then plot these average predicted salary profiles in Figure 2. Salary adjusted for inflation using the CPI-U with base years 1982-84.

Figure 3: Average Predicted After-Postdoc Salary Over Career by Postdoc-Trained Status: Experience as Years Since PhD

Notes: Figure 3 shows the average of predicted salary profiles for biomedical doctorates with and without postdoc training generated by an augmented version of the regression model found in Column (4) of Table 3 where we allow for interactions between the indicator variable for postdoc training and quartic polynomial in experience. The plots are generated by the following process: For each doctorate in the given employment sector sample, we generate two predictions of log(salary) in each year since PhD. The first prediction gives the log(salary) predicted if the person is assumed to have done a postdoc and the second prediction gives the log(salary) predicted if the person did not do a postdoc. Then, we average the predicted log(salary) across individuals in the given employment sector in each year since PhD and apply the exponential function to translate log(salary) into salary. We then plot these average predicted salary profiles in Figure 3. The employment sector subsamples are based on each doctorate's sector of employment in the given year, rather than the sector of employment at ten years post-PhD, in the underlying regression models used to generate the predictions Salary adjusted for inflation using the CPI-U with base years 1982-84.

Figure 4: Average Predicted After-Postdoc Salary Over Career by Postdoc-Trained Status: Experience as Years of Post-PhD Nonpostdoc Employment

Notes: Figure 4 shows the average of predicted salary profiles for biomedical doctorates with and without postdoc training generated by an augmented version of the regression model found in Column (4) of Table 3 where we allow for interactions between the indicator variable for postdoc training and quartic polynomial in experience. The plots are generated by the following process: For each doctorate in the given employment sector sample, we generate two predictions of log(salary) in each year since PhD. The first prediction gives the log(salary) predicted if the person is assumed to have done a postdoc and the second prediction gives the log(salary) predicted if the person did not do a postdoc. Then, we average the predicted log(salary) across individuals in the given employment sector in each year since PhD and apply the exponential function to translate log(salary) into salary. We then plot these average predicted salary profiles in Figure 4. The employment sector subsamples are based on each doctorate's sector of employment in the given year, rather than the sector of employment at ten years post-PhD, in the underlying regression models used to generate the predictions. Salary adjusted for inflation using the CPI-U with base years 1982-84.

Tables

Table 1: Summary Statistics by Postdoc-Trained Status: Academia and Industry

Employment Sector:	Academia		Industry	
Group:	Postdoc	Nonpostdoc	Postdoc	Nonpostdoc
Foreign-born	0.25	0.17	0.27	0.22
Temp. Resident	0.13	0.06	0.14	0.09
Age at PhD	30.53	33.19	30.26	31.55
Female	0.39	0.40	0.39	0.36
Asian	0.17	0.10	0.21	0.17
Minority	0.08	0.09	0.06	0.11
PhD Length	6.77	7.97	6.57	7.45
Married at PhD	0.55	0.66	0.53	0.60
Child at PhD	0.32	0.47	0.28	0.41
Fellowship during PhD	0.17	0.17	0.15	0.15
RA during PhD	0.30	0.21	0.33	0.27

Father's Highest Education: > BA	0.34	0.30	0.32	0.30
N	2192	674	1193	593

Notes: This table reports weighted means for postdoc-trained and nonpostdoc-trained biomedical doctorates in the analytical sample by employment sector, where the weights used for each doctorate are those from the most recent SDR wave wherein each doctorate is observed. Sample counts are unweighted. For each cell, approximately 10% of PhD length calculations were imputed at the mean value (seven years) for the analytical sample. Individuals who work in both industry and a nonpostdoc job in academia are included in both subsamples to be consistent with the samples underlying the results in Table 3. Summary statistics for the full sample and "Gov't/Nonprofit" sector are reported in Table A.2.

Table 2: Impact of Postdoc Training on Salary

Notes: This table reports regressions results based on equation (1) where our sample includes all biomedical doctorates in the SDR graduating between 1980 and 2006. For each doctorate, we keep only those person-year observations corresponding to years after any and all years employed as a postdoc. For specifications (1) and (2), we drop all observations within the first six years after Ph.D. so that postdoc and nonpostdoc observations are comparable. Subsamples are based on the employment sector associated with each person-year observation. Robust standard errors clustered at individual-level are in parentheses. Estimates produced using survey weights. Specifications (1) - (4) include all controls listed in Table A.1.

PhD University	✓	✓	✓	✓

Notes: This table reports regressions results where the dependent variable for each column is an indicator variable for the type of job given by the column name. Observations are person-level. The samples used for the "Academic" and "Tenure-Track" columns include biomedical doctorates in the SDR graduating between 1980 and 2007 for whom we have observed for at least 10 years post-PhD. The sample used for the "Tenured" column includes biomedical doctorates in the SDR graduating between 1980 and 2006 who report being on the tenure track at some point and then later report either 1) being in a tenured position or 2) not in a tenured position and no longer on the tenure track. The sample used for the "Industry" column includes biomedical doctorates in the SDR graduating in or after 1980 who ever report working in industry. For each column, Panel B adds an additional restriction that the type of job be one where the doctorate's primary work activity is R&D in order for the indicator variable to equal 1. Robust standard errors clustered at the field-cohort level are in parentheses. Specifications (1) - (4) include all controls listed in Table A.1.
* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Controlled	-0.117	0.246	-0.00836	0.314	-0.158	0.400	-0.106	0.540
R_{max}	0.320		0.408		0.521		0.702	
$\hat{\theta}(\delta = 1, R_{max})$	-0.174		-0.0775		-0.262		-0.510	
N	22512		11941		6708		3863	

Notes: We test if the results in column (2) of Table 3 are robust to allowing for selection on unobservables using the methods developed in Oster (2019). We report both the estimated impact of postdoc training on log(salary) and the R^2 for regressions without any controls ("uncontrolled") and with all of the controls ("controlled") in our most general regression specification. We then calculate the estimated effect of postdoc training on after-postdoc salary given an equal degree of selection on unobservables as selection on observables ($\delta = 1$) and where we select R_{max} as equal to $1.3 * \tilde{R}^2$ where $\tilde{R}^2$ is the R^2 obtained from the controlled regression.

Notes: We test if the results in Panel B of Table 4 are robust to allowing for selection on unobservables using the methods developed in Oster (2019). We report both the estimated impact of postdoc training on obtaining research jobs and the R^2 for regressions without any controls ("uncontrolled") and with all of the controls ("controlled") in our most general regression specification. We then calculate the level of selection on unobservables necessary to yield an estimated impact of exactly zero where we select R_{max} as the $1.3 * \tilde{R}^2$ where $\tilde{R}^2$ is the R^2 obtained from the controlled regression.

Notes: This table reports regressions results based on equation (1) where our sample includes all biomedical doctorates in the SDR graduating between 1993 and 2006 who are observed in at least two of their first six years post-PhD. For each doctorate, we keep only those person-year observations corresponding to years after any and all years employed as a postdoc, and we drop all observations within the first six years after Ph.D. so that postdoc and nonpostdoc observations are comparable. Subsamples are based on the employment sector associated with each person-year observation. Robust standard errors clustered at individual-level are in parentheses. Estimates produced using survey weights. Specifications (1) - (6) include all controls listed in Table A.1.
* $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

Table 12: Primary Tasks Performed by Doctorates Working in Industry Before and After the First Six Years Post-PhD by Postdoc-Trained Status

	First Six Years		After Six Years	
Work Activity	No Pdoc	Pdoc	No Pdoc	Pdoc
Accounting, Finance, and Contracts	NA	NA	4.21%	4.21%
Applied Research	45.98%	28.86%	40.23%	52.91%
Basic Research	5.75%	75.15%	4.21%	10.22%
Computer Applications	6.90%	2.00%	7.28%	6.21%
Development	18.39%	NA	27.59%	25.85%
Design	NA	NA	NA	4.61%
Human Resources	NA	NA	NA	NA
Managing People or Projects	19.16%	NA	38.70%	37.27%
Production, Operations, Maintenance	NA	NA	NA	3.81%
Quality or Productivity Management	NA	NA	4.60%	5.81%
Sales, Purchasing, Marketing	4.98%	NA	8.05%	8.82%
Professional Services	24.90%	4.21%	31.80%	20.64%
Teaching	NA	NA	NA	NA
Other	7.28%	NA	10.34%	9.02%
N	261	499	261	499

Notes: In this table, we calculate the proportion of postdoc-trained and non-postdoc trained biomedical doctorates that report each given task as their primary work activity at least once 1) in their first six years post-PhD and 2) after their first six years post-PhD. We restrict the sample to biomedical doctorates that are employed in industry at 10 years post-PhD, as in Column (2) of Table A.4. For postdocs, we only consider observations in the first six years post-PhD that correspond to years employed as a postdoc; after six years post-PhD, we only consider observations corresponding to years after any and all years employed as a postdoc, and where the doctorate is employed in industry. For nonpostdocs, we only consider observations corresponding to years where the person is employed in industry. We also require that a person shows up in the analytical sample within the first six years post-PhD — this means that doctorates graduating between 1981 and 1986 will be automatically excluded from this analysis since the first wave we include in this study is SDR 1993. "NA" reported in cells of insufficient size to be disclosed.

Table 13: Tasks Performed by Doctorates Working in Industry Before and After the First Six Years Post-PhD by Postdoc-Trained Status

	First Six Years		After Six Years		Task Change	
Work Activity	No Pdoc	Pdoc	No Pdoc	Pdoc	No Pdoc	Pdoc
Accounting, Finance, and Contracts	22.61%	2.61%	47.13%	39.68%	24.52	37.07
Applied Research	67.82%	73.95%	72.03%	78.76%	4.21	4.81
Basic Research	33.33%	90.98%	37.93%	53.31%	4.60	-37.68
Computer Applications	32.95%	28.66%	28.35%	30.66%	-4.60	2.00
Development	55.56%	21.64%	65.13%	69.94%	9.58	48.30
Design	33.72%	18.64%	38.31%	48.30%	4.60	29.66

Managing People or Projects	72.41%	40.68%	85.06%	85.17%	12.64	44.49
Production, Operations, Maintenance	11.11%	7.01%	14.94%	30.06%	3.83	23.05
Quality or Productivity Management	29.12%	5.61%	39.85%	42.08%	10.73	36.47
Sales, Purchasing, Marketing	26.44%	4.01%	38.70%	35.67%	12.26	31.66
Professional Services	37.16%	8.82%	47.51%	35.67%	10.34	26.85
Teaching	21.07%	19.64%	25.29%	27.86%	4.21	8.22
Other	12.26%	3.61%	21.46%	21.24%	9.20	17.64
N	261	499	261	499	261	499

Notes: In this table, we calculate the proportion of postdoc-trained and non-postdoc trained biomedical doctorates that report spending at least 10% of their work time engaged in the given activity at least once 1) in their first six years post-PhD and 2) after their first six years post-PhD. For both postoc-trained and nonpostdoc-trained biomedical doctorates, we then report the percentage-point difference between the fraction of each performing each task within and after their first six years post-PhD, and refer to this measure as the "task change" of each group. We restrict the sample to biomedical doctorates that are employed in industry at 10 years post-PhD, as in Column (2) of Table A.4. For postdocs, we only consider observations in the first six years post-PhD that correspond to years employed as a postdoc; after six years post-PhD, we only consider observations corresponding to years after any and all years employed as a postdoc, and where the doctorate is employed in industry. For nonpostdocs, we only consider observations corresponding to years where the person is employed in industry. We also require that a person shows up in the analytical sample within the first six years post-PhD — this means that doctorates graduating between 1981 and 1986 will be automatically excluded from this analysis since the first wave we include in this study is SDR 1993.

A Appendix Figures and Tables

Figure A.1: Number of PhDs Awarded in Biomedical Fields by Year

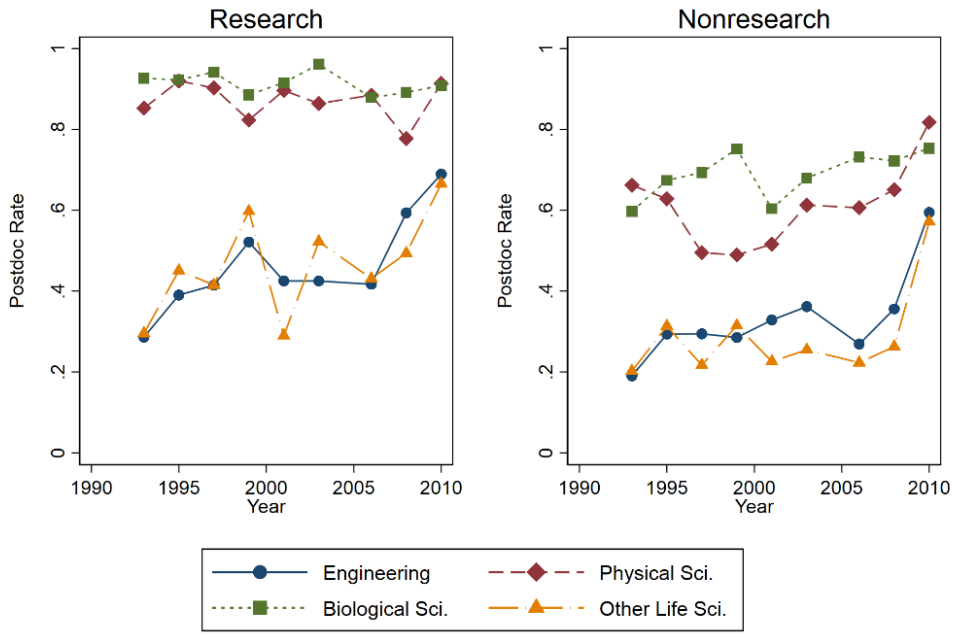

Notes: Figure A.1 shows the number of PhDs awarded in Biological and Biomedical Sciences in each year. Data is from the NSF's Survey of Earned Doctorates (SED).

Figure A.2: Postdoc Rate and Length by S&E Field

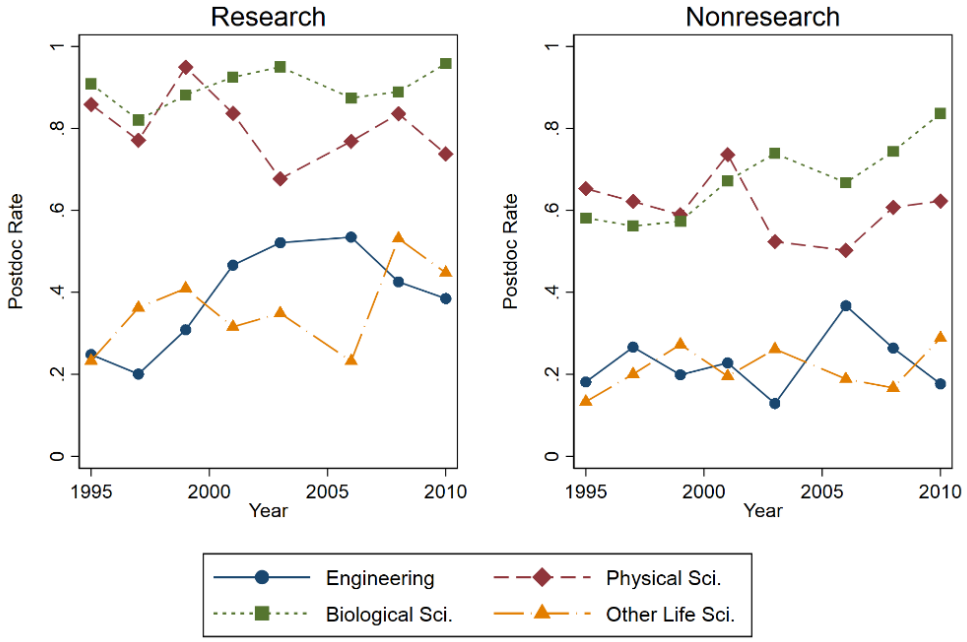

Notes: The left panel of Figure A.2 shows the proportion of doctorates in each PhD cohort that ever take a postdoc by broad field of study. The right panel show the mean length of postdoc training for all postdoc-trained PhD cohort members by broad field of study. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure A.3: Postdoc Rate of New Tenure-Track Faculty by S&E Field

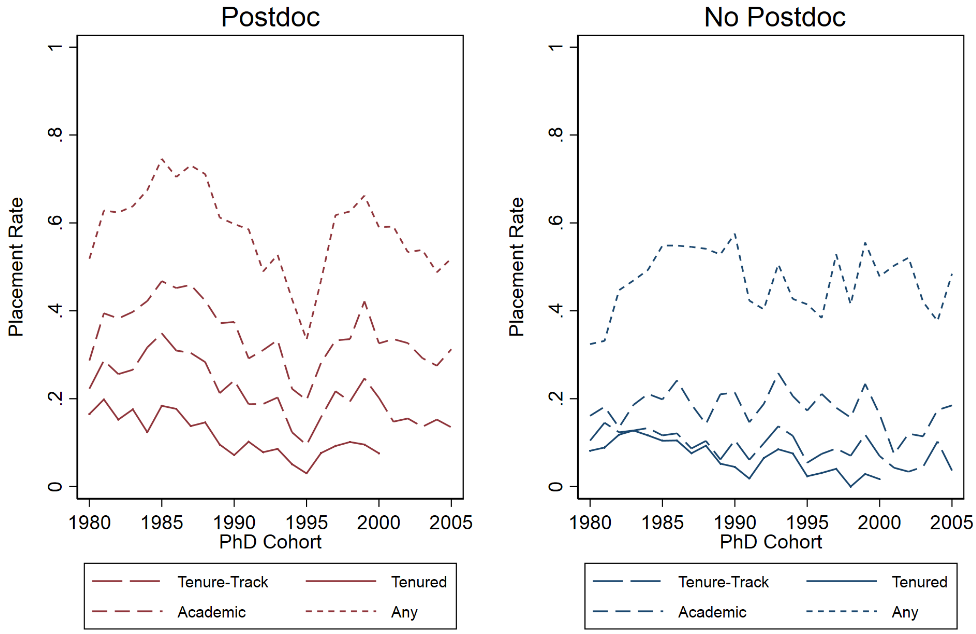

Notes: Figure A.3 shows proportion of individuals that first report being employed in a tenure-track position in a given SDR wave by broad field of study. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure A.4: Postdoc Rate of Newly Tenured Faculty by S&E Field

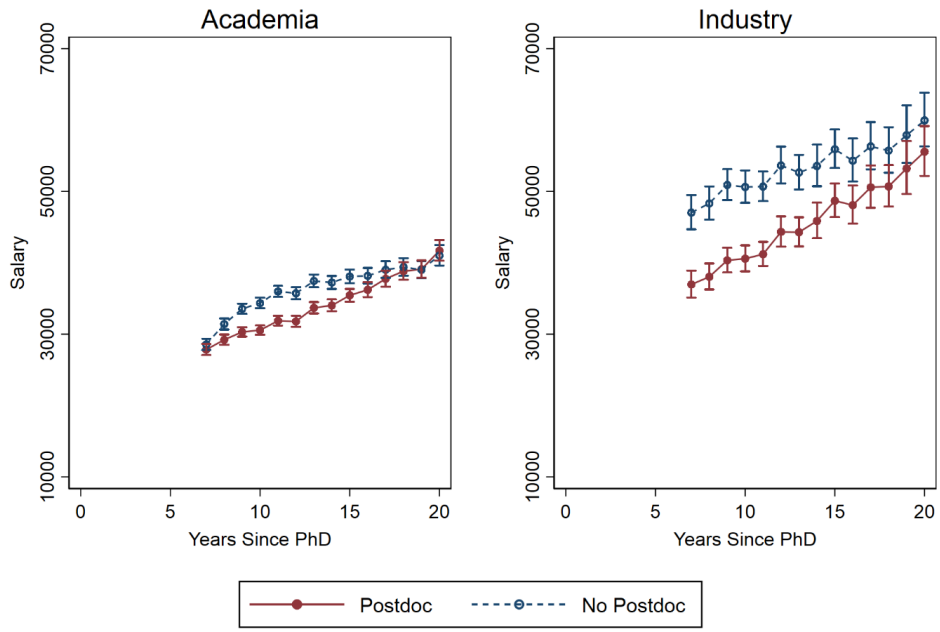

Notes: Figure A.4 shows proportion of individuals that first report being employed in a tenured position in a given SDR wave by broad field of study. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure A.5: Research Job Placement Rates by Prior Postdoc Status

Notes: Figure A.5 shows proportion of biomedical doctorates who take the indicated academic research position (excluding postdoc positions) within 15 years post-PhD by PhD cohort and whether individual has postdoc training. We require that we observe an individual for the full 15 years post-PhD for "Tenured" calculations, but only require at least 10 years of observations for the other positions since these positions typically take less time to obtain relative to a tenured position. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure A.6: Average Predicted After-Postdoc Salary Over Career by Postdoc-Trained Status: Experience as Years Since PhD with Alternative Sector Subsamples

Notes: See notes for Figure 3. The only change in Figure A.6 relative to Figure 3 is that we define the employment sector subsamples based on each doctorate's sector of employment at ten years post-PhD, rather than the sector of employment in the given year, in the underlying regression models used to generate the predictions. Salary adjusted for inflation using the CPI-U with base years 1982-84.

Table A.1: Regression Controls

Variable Name	Variable Definition
female	Indicator variable for if reported as a female
age_phd	Age when earned PhD
asian	Indicator variable for if race reported as "Asian"
race_minority	Indicator variable for if race reported as non-Asian minority
foreign	Indicator variable for if reported as foreign-born
temp_res	Indicator variable for if reported being a temporary resident when earned PhD
married_phd	Indicator variable for if reported being married when earned PhD
child_phd	Indicator variable for if reported any children living at home when earned PhD
married_child_phd	Indicator variable for if reported being married and having children at home when earned PhD
female_interactions	A set of two-way interaction terms between female and all controls listed above
phd_length	Number of years between entering PhD program and earning PhD
phd_length_miss	Indicator variable for if PhD length missing — phd_length assigned average value when phd_length_miss=1
fellow	Indicator variable for if primary source of support during PhD was a fellowship or scholarship
TA	Indicator variable for if primary source of support during PhD was a teaching assistantship
RA	Indicator variable for if primary source of support during PhD was a research assistantship
edmother_ba	Indicator variable for if mother's highest level of education is Bachelor's degree
edmother_ma	Indicator variable for if mother's highest level of education is Master's degree
edmother_prof	Indicator variable for if mother's highest level of education is Professional degree
edmother_phd	Indicator variable for if mother's highest level of education is PhD
edfather_ba	Indicator variable for if father's highest level of education is Bachelor's degree
edfather_ma	Indicator variable for if father's highest level of education is Master's degree
edfather_prof	Indicator variable for if father's highest level of education is Professional degree
edfather_phd	Indicator variable for if father's highest level of education is PhD
profmd	Indicator variable for if earning or have already earned a professional degree such as MD
yrs_since_phd	Number of years since earned PhD
yrs_since_phd_sq	(Number of years since earned PhD)^2
yrs_since_phd_cub	(Number of years since earned PhD)^3
yrs_since_phd_quart	(Number of years since earned PhD)^4
year	A set of normalized year fixed effects
phdfy	A set of PhD cohort (i.e. graduation year) fixed effects
phdfield	A set of SED fine field of study fixed effects

Notes: This table lists the controls used in the salary regressions. These controls are also used in the research job regressions (excluding yrs_since_phd, yrs_since_phd_sq, yrs_since_phd_cub, yrs_since_phd_quart, and year).

Table A.2: Summary Statistics by Postdoc-Trained Status: Full Sample and Government/Nonprofit Subsample

Employment Sector:	Full Sample		Gov't/Nonprofit	
Group:	Postdoc	Nonpostdoc	Postdoc	Nonpostdoc
Foreign-born	0.25	0.20	0.23	0.17
Temp. Resident	0.13	0.07	0.10	0.06
Age at PhD	30.47	32.69	30.75	33.26
Female	0.39	0.38	0.40	0.36
Asian	0.18	0.13	0.17	0.10
Minority	0.08	0.10	0.07	0.10
PhD Length	6.69	7.75	6.81	7.96
Married at PhD	0.53	0.63	0.51	0.59
Child at PhD	0.30	0.45	0.30	0.40
Fellowship during PhD	0.17	0.17	0.19	0.15
RA during PhD	0.31	0.23	0.30	0.22
TA during PhD	0.12	0.14	0.11	0.15
Mother's Highest Education: BA	0.22	0.20	0.21	0.19
Mother's Highest Education: > BA	0.19	0.16	0.21	0.19
Father's Highest Education: BA	0.23	0.21	0.20	0.24
Father's Highest Education: > BA	0.34	0.30	0.35	0.27
N	3420	1358	809	360

Notes: This table reports weighted means for postdoc-trained and nonpostdoc-trained biomedical doctorates in the analytical sample by employment sector, where the weights used for each doctorate are those from the most recent SDR wave wherein each doctorate is observed. Sample counts are unweighted. For each cell, approximately 10% of PhD length calculations were imputed at the mean value (seven years) for the analytical sample.

Notes: In this table, we compute bias-adjusted effects of postdoc training on after-postdoc training for alternative levels of selection on unobservables relative to observables (δ) and alternative levels of R_{max}. We use $\tilde{R}^2$ to denote the R^2 from the regression results in column (2) of Table 3. "Person FE R^2" refers to the R^2 obtained from a regression of log(salary) on person fixed effects and a quartic polynomial in experience.

Notes: Table A.3 reports coefficient estimates on the (primary) task history controls included in the regression whose main results are report in column (2) of Table 14. Applied research is base case so estimates can be interpreted as value of spending an additional year in a job with the given primary task relative to a job where applied research is the primary task. Robust standard errors clustered at individual-level are in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

B Supplementary/Online Appendix

B.1 Identifying Postdocs and Postdoc Length in SDR-SED Data

Our dataset is made up of three different sources that contain information about a doctorate's postdoc status. The first source is the SED, wherein respondents are asked "What best describes your (within the next year) postgraduate plans?" and "What is the status of your postgraduate plans (in the next year)?" Starting in the SED in 2004, respondents are also asked "Do you intend to take a 'postdoc' position?". Using these questions, we assign a person as doing a postdoc if the respondent says that, post-graduation, he/she plans to do either a: 1) postdoc fellowship, 2) postdoc research associateship, 3) traineeship, or 4) internship/ clinical residency, and also states that he/she 1) will be either returning to present employment, 2) has accepted a position, or 3) is in negotiation with one or more specific organizations.

The second source containing information on postdoc status is the SDR. In each SDR wave, doctorates are asked whether they are currently working and whether their current job is a "postdoc." If a doctorate reports being in a postdoc job in any SDR wave, then we consider them to have done a postdoc. The third source comes from the Special Topic Module included on the SDR 1995 and 2006 waves wherein respondents are asked how many postdoc positions they have ever held and the starting and ending dates for their last three postdoc positions. We follow Kahn and Ginther (2017) in referring to these as the SDR Retrospective Surveys. If a doctorate reports having done at least one postdoc on either SDR Retrospective Survey, then we count that person as having done a postdoc. If a doctorate reports never having done a postdoc on the Retrospective Surveys, then we label the person as having never done a postdoc. In rare cases, sources disagree about whether a person has ever done a postdoc. If SED states that a person plans to do a postdoc, but then they never report doing a postdoc in any SDR wave and they claim to have never taken a postdoc position in the SDR Retrospective Surveys, then we label the person as never

having done a postdoc. If a doctorate ever claims to have done a postdoc in any SDR wave (including the SDR Retrospective Surveys), then we label them as having done a postdoc.

Next, we seek to determine which years a person was employed as a postdoc. We create a variable ("pdoc_year") that equals one if the doctorate was in a postdoc in the given year and equals zero if the doctorate was not in a postdoc in the given year. Once we form this variable, we will take its sum across years for each doctorate to measure each doctorate's duration (or "length") of postdoc training. If a person was found to have never done a postdoc (pdoc==0), then we label the person as not being employed in a postdoc for all years for which they appear (i.e., pdoc_year==0 for all years). If the person could be identified as a postdoc based solely on information from the SED, then we labeled the year of PhD receipt as being a year that the doctorate was employed as a postdoc. For those who report currently being in a postdoc position in an SDR wave, we have the year that they began that current employment and so label all years from the start of employment to that SDR wave as years in a postdoc. For doctorates in the SDR 1995 and/or 2006 wave ("SDR Retrospective Surveys"), we have information on the start and end dates of a person's last three postdoc positions, and so label any years within any of the reported postdocs as postdoc years. Additionally, we consider all years after the end of the last reported postdoc on the SDR Retrospective Surveys as being years where a doctorate was not in a postdoc, assuming we have no other evidence to suggest the person took up an additional postdoc after that time. Similarly, for doctorates who report having done at most three postdocs throughout their career in the SDR Retrospective Surveys, we label years preceding the start of their first reported postdoc as years that the person was not in a postdoc, assuming no additional evidence to suggest otherwise. Additionally, we label any years 1) between the end of the 2nd most recent postdoc and the start of the most recent postdoc or 2) between the end of the 3rd most recent postdoc and the start of the 2nd most recent postdoc as "non-postdoc" years. Lastly, we label as non-postdoc years any SDR year where a doctorate reports not being currently employed in a postdoc position.

In addition, we impute whether a year is or is not a postdoc year in special cases to avoid sample attrition. The need for imputation is due to two features of the SDR. First, the SDR is typically biennial, and so there is usually one year in between SDR waves, although there are two cases where there are two-year gaps: between SDR 2003 and 2006 and between SDR 2010 and 2013. Second, new sample members to the SDR have typically been added between one and three years after PhD receipt. This means that some doctorates may have one or two years between their PhD graduation year and entry into the SDR where postdoc status is missing.[64]

Our imputation strategy is as follows: if a doctorate reports not being in a postdoc in both the SDR wave before and after the gap year(s), then those gaps years are considered as non-postdoc years. Similarly, if a person reports being in a postdoc in both the SDR wave before and after the gap year(s), then those gap years are considered postdoc years. If a doctorate reports doing a postdoc in the SDR wave before a gap year, but reports not doing a postdoc in the SDR wave after the gap year, then we split the difference for gap years by assigning a value of 0.5 to our postdoc year variable. If a doctorate is surveyed in the SDR within three years, but has gap years preceding appearance in the SDR, then we assign a value of 0.5 if the person reports a postdoc position in his/her first SDR wave and assign a value of 0 if the person reports no postdoc position in his/her first SDR wave.[65] For biomedical doctorates first sampled in the SDR prior to SDR 2010, we are able to identify if a doctorate was ever a postdoc in 99% of cases. In 86% of cases, we are able to identify or impute whether or not a biomedical doctorate is employed as a postdoc in each year since PhD graduation.

[64] Starting with SDR 2010, doctorates obtaining PhDs more than three years prior to the survey date were newly sampled; for these cases, there are many years where we cannot determine postdoc status, and so we will exclude these doctorates from our analytical sample.

[65] After our imputation strategy, the majority of doctorates who ever have a year where we fail to determine postdoc status are those who first appear in the SDR in the 2015 wave. The SDR 2015 wave was unique in that 80% of the SDR 2015 sample members were new to the survey, whereas in past cycles around 10% of the sample members were new. This was due to the SDR being expanded from 47,000 to 120,000 members, with members being added even when having graduated much earlier than 2015. Given this large increase in the number of new SDR members, it would be valuable for the SDR to once again include questions about previous postdoc experience, as was done for the 1995 and 2006 waves.

B.2 Biomedical Postdocs: Who They Are, Where They Work, and What They Do

Among biomedical doctorates, who are the most likely to pursue postdoc training? Figure B.1 breaks down biomedical postdocs and nonpostdocs by their foreign-born status, sex, race, marital status at time of PhD, and whether a child was present at home at time of PhD.[66] Since 1980, the female-shares of biomedical doctorates taking and not taking postdoc positions have both risen, although a recent gap has emerged with the female share of nonpostdocs exceeding that of postdocs. The foreign-born shares of postdocs and nonpostdocs have both risen over time, with postdocs tending to have a higher concentration of foreign-born doctorates compared to nonpostdocs.[67] The trends in the Asian-share of postdocs and nonpostdocs roughly mirrors the foreign-born trends, and these two trends are likely related as Asian countries including China, India, South Korea, and Taiwan make up the top countries-of-origin for foreign biomedical PhD students in the US (National Science Board, 2018). Postdocs appear less likely than nonpostdocs to be married at time of PhD and to have a child at home at time of PhD, and Figure B.2 shows that the average age at PhD graduation for nonpostdocs has consistently exceeded that of postdocs. Altogether, these trends make intuitive sense — individuals that are younger and have potentially fewer financial responsibilities (nonmarried with no children) at the time of graduation are more likely to do postdocs, as are foreign-born individuals whose ability to remain in the United

[66] Here postdoc refers to biomedical doctorates in a given cohort who ever go on to do postdocs. Similarly, nonpostdocs refers to those biomedical PhDs in a given cohort that never receive postdoc training.

[67] These data are for individuals first appearing in the SDR prior to 2010. In 2010, the SDR began sampling US-trained PhDs who reside outside of the United States, whereas previous waves only included US-trained PhDs residing in the US after graduation. Due to this sampling change, the NSF recommends caution when analyzing and interpreting pre- and post-2010 trends. Also, the SDR 2010 introduced new sample members that had graduated as far back as 2001; we are not able to reliably identify whether these individuals were ever employed as postdocs given that they are first sampled in the SDR many years after graduation and were not part of the SDR 2006 wave where doctorates were asked whether they had previously worked as a postdoc. We therefore restrict the graphs to pre-SDR 2010 data. We also limit the sample to individuals who appear in the SDR in 1993 at the earliest due to survey format changes in 1993 and sampling changes in 1991. (`https://nsf.gov/statistics/srvydoctoratework/#micro&tabs-1&sd`).

States may be enhanced by taking an academic postdoc position exempt from H-1B quotas.[68]

Postdoc employment involves working long hours for low pay: Figure B.3 shows that between 1995 and 2013, biomedical doctorates age 28-32 employed in postdoc positions typically worked about 10% more hours a week for 50% of the salary compared to their counterparts in industry. These demanding working conditions have typically been justified by the traditional view that postdoc positions are apprenticeships that provide researchers training in skills necessary to become independent researchers.[69] However, as Figure A.5 shows, only a small fraction of biomedical postdocs actually become independent researchers in the traditional academic setting.

After completing a postdoc, where do biomedical doctorates work? Figure B.4 shows that postdoc-trained biomedical doctorates between the ages of 30 and 40 are slightly more concentrated in academic jobs than those of the same age with no postdoc training, and that a significant fraction of both occupy jobs in industry, with only a small fraction in government and nonprofits.[70] Figure B.5 shows that, on average, biomedical doctorates age 30 to 40 working in industry have higher salary compared to their counterparts in academia.[71] While the share of biomedical doctorates going into each sector are similar regardless of postdoc-trained status, the tasks performed by each significantly differ. Figure B.6 shows that most postdoc-trained biomedical doctorates age 30 to 40 in academia report their primary work activity as research, and that this share is roughly double that of biomedical doctorates without postdoc training. Meanwhile, the plurality of nonpostdocs in academia are primarily engaged in teaching. These results suggest that postdoc training improves

[68] Jobs at academic institutions have been exempt from H-1B visa caps since fiscal year 2001. Additionally, there are no statutory caps on J-1 visas which are a popular alternative to the H-1B visa for foreign-born postdocs working in the US.

[69] The NSF and NIH define a postdoctoral scholar as "an individual who has received a doctoral degree (or equivalent) and is engaged in a temporary and defined period of mentored advanced training to enhance the professional skills and research independence needed to pursue his or her chosen career path" (Bravo and Olsen, 2007).

[70] Throughout this paper, we focus on academia and industry as these are the two main sectors employing biomedical doctorates.

[71] For purposes of Figure B.5, individuals employed as postdocs in the given year are excluded from the calculation of the average salary for that year.

one's chances of securing a research job in academia, but that a postdoc is not necessary for an academic teaching position.[72] As may be expected, Figure B.9 shows that research positions in academia tend to pay more than teaching positions, meaning that taking a postdoc position may increase a biomedical doctorate's after-postdoc salary in academia through an enhanced ability to find an after-postdoc research position.[73]

Figure B.10 shows the primary work activities performed by postdoc-trained and non-postdoc-trained biomedical doctorates age 30 to 40 working in industry. In any given year, biomedical doctorates with postdoc training are more heavily concentrated in research positions in industry, while nonpostdoc-trained individuals are more likely to be performing professional services (e.g., healthcare services). Furthermore, Figure B.11 shows that the number of biomedical PhDs in research-oriented jobs is growing and that, unlike researchers in other fields, a majority of biomedical PhDs conducting research in industry have postdoc training. These findings suggest that postdoc training may not only improve one's chances of acquiring a research job in academia but may also improve one's chances at securing a research job in industry.[74]

Among biomedical doctorates whom acquire a research position in academia or industry, do postdoc trained individuals perform any differently than those without postdoc training? Figure B.13 shows that among biomedical doctorates age 30 to 55 working in research jobs, those with postdoc training are more likely to produce — and tend to produce more — peer-reviewed papers in both academia and industry. Figure B.14 shows that postdocs in industry are more likely to be named as an inventor on patent applications and granted

[72]Figure B.7 shows that among biomedical doctorates working in research-focused jobs in academia, postdoc-trained biomedical doctorates are much more likely to be working in jobs focused on basic research rather than applied research compared to nonpostdoc-trained counterparts. See Figure B.8 for comparable results for those employed in industry research jobs, where jobs focused on basic research are much more rare.

[73]Figure B.9 excludes salary observations for those that are employed as a postdoc in the given year.

[74]This finding is notable: Sauermann and Roach (2016) survey PhD students from 39 research-intensive universities and find that 78% of respondents in the biological sciences believed that at least 1 year of postdoc training was required for a PhD-level R&D position in industry. The authors lament that "unfortunately, there is little empirical evidence showing whether the postdoc benefits graduates pursuing nonacademic careers."

patents. Figure B.15 shows that postdocs have more patents granted on average, although the rate at which granted patents result in commercial products is higher for nonpostdocs.[75] Nonetheless, the fact that postdocs are more likely to publish peer-reviewed research — and publish more of it — and are more likely to engage in patenting activity, suggests that the research positions occupied by postdoc trained doctorates in industry may either be more research-intensive than nonpostdoc research positions, or that postdocs are more scientifically productive than nonpostdocs in similar industry research positions.

How do the earnings in research-oriented industry jobs compare to nonresearch industry jobs? Figure B.16 shows that, on average, research jobs in industry pay less in terms of salary compared to nonresearch jobs, and Figure B.17 shows that this relationship holds for both postdoc-trained and nonpostdoc-trained biomedical doctorates age 30 to 40. This pattern is consistent with the finding in Stern (2004) that PhD biologists pay a compensating differential to participate in science. However, Figure B.17 also shows that the average salary for postdocs is less than that of their nonpostdoc counterparts in most years regardless of the research orientation of the job, which is consistent with a postdoc penalty on after-postdoc salary in industry that cannot be explained by a compensating differential for research jobs.

How do earnings evolve over a postdoc's career compared to that of a nonpostdoc? Figure 1 shows the median earnings over time for biomedical doctorates by employment sector and whether they take a postdoc position.[76] We find that postdoc-trained biomedical doctorates in industry and academia have similar median earnings in their first three years after PhD, which is when most would be employed as postdocs. We can see that postdoc-trained biomedical doctorates in academia and industry both start at a lower salary than their nonpostdoc-trained counterparts, but that nonpostdoc-trained biomedical doctorates

[75]The SDR asks individuals about the number of patent applications, patents granted, and granted patents resulting in a commercial product in the last 5 years. If postdocs are more likely than nonpostdocs to be named as an inventor on longer-term projects, this could explain why the commercialization rate for postdocs is lower than nonpostdocs. It might not be that patents associated with postdocs are not able to be commercialized, but that it takes longer than five years for this to occur. Patenting information is only available for four waves of the SDR: 1995, 2001, 2003, and 2008.

[76]Biomedical doctorates are associated with the employment sector (academia or industry) that they occupy at 10 years post-PhD.

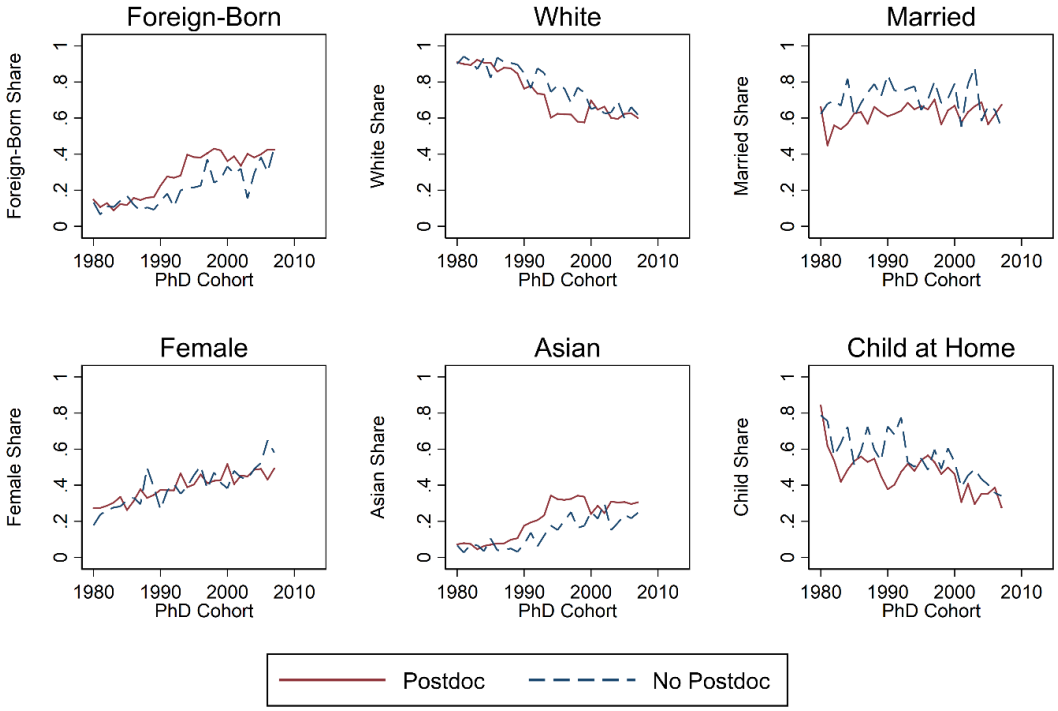

attract a higher starting salary in industry as compared to academia. Industry earnings profiles are steeper than academic earnings profiles, indicating stronger earnings growth in that sector. Interestingly, it appears that postdoc median earnings catch up with and then begin to exceed the median earnings of nonpostdocs in the academic sector 10 years after graduation. In industry, it appears that the gap between the median earnings of postdoc-trained and nonpostdoc-trained biomedical doctorates is persistent. This suggests that the cost of doing a postdoc for those that end up going to industry is not just forgone earnings during their years as a postdoc, but also lower after-postdoc salary possibly due to deferred on-the-job training in industry.

In summary, the trends in the data show the following: Postdoc-trained biomedical doctorates are more heavily concentrated in research positions both in academia and industry compared to their nonpostdoc-trained counterparts. Biomedical doctorates working in industry earn more than those in academia, and those in industry (academic) research jobs tend to make less (more) than those in industry (academic) nonresearch jobs. Nonpostdoc-trained biomedical doctorates in both research and nonresearch positions in industry tend to earn more than their postdoc-trained counterparts. Postdoc-trained biomedical doctorates working in industry are more likely to publish peer-reviewed research, publish more papers, and are more likely to engage in at least some patenting activity compared to nonpostdoc-trained biomedical doctorates in industry.[77] Postdoc-trained biomedical doctorates in industry consistently earn less than their nonpostdoc-trained counterparts, while postdoc-trained biomedical doctorates in academia start with a lower salary than their nonpostdoc-trained counterparts, but catch up and then exceed them in terms of salary by 10 years after PhD. Altogether, these facts suggest that postdoc training holds value for obtaining a research-oriented career, whether that be in academia or industry, but that there is a persistent postdoc penalty on after-postdoc salary in industry for biomedical doctorates.

[77] In addition to these facts, Figure B.18 and Figure B.19 show that postdocs may be more likely to work in industry jobs closely related to their field of study and to work in larger firms, respectively.

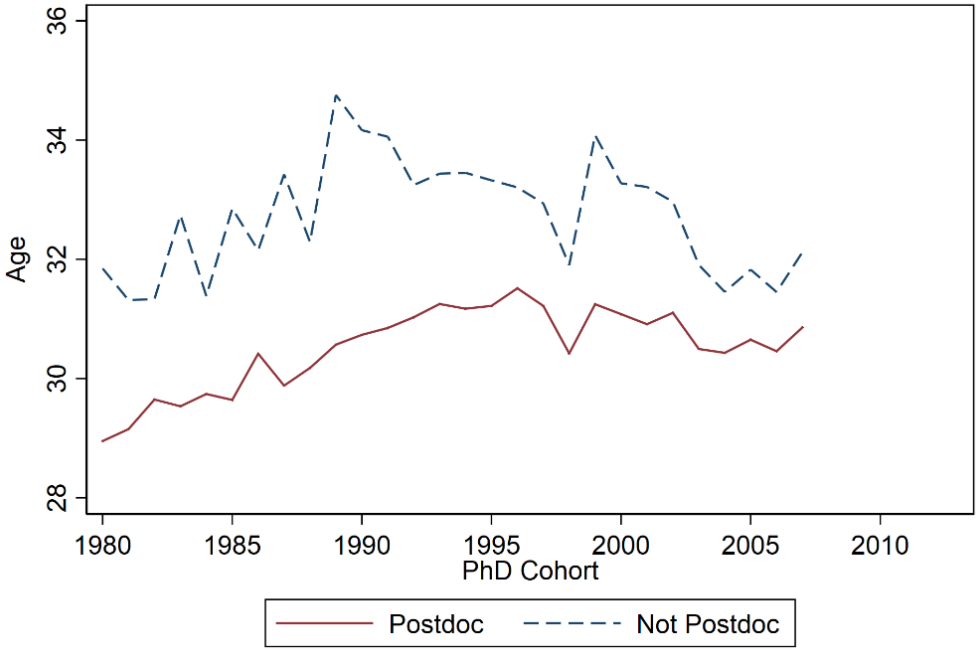

B.3 Supplementary Figures

Figure B.1: Demographics by Postdoc Status and Cohort

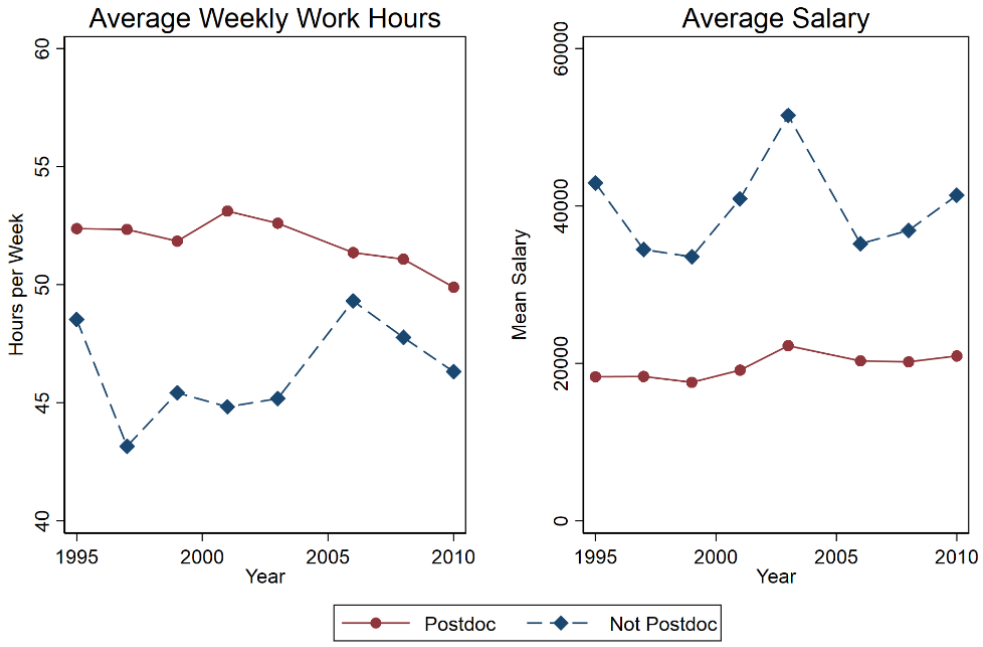

Notes: Figure B.1 shows the proportion of biomedical doctorates with various background characteristics by PhD cohort and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.2: Average Age at PhD Receipt by Postdoc Status

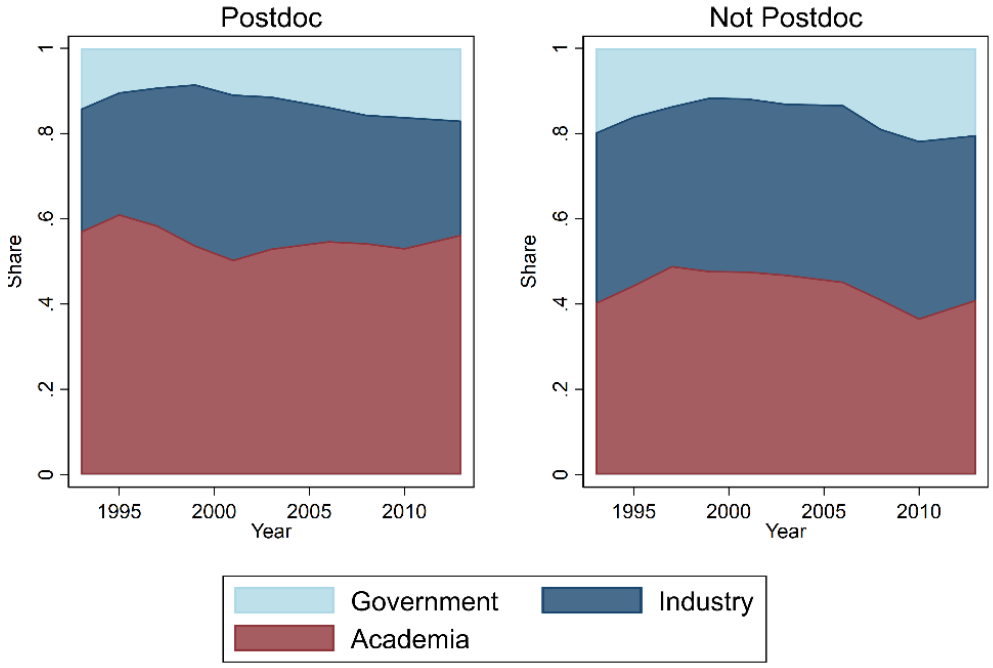

Notes: Figure B.2 shows the average age of biomedical doctorates at time of PhD completion by PhD cohort and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.3: Work Hours and Pay by Postdoc Employment Status

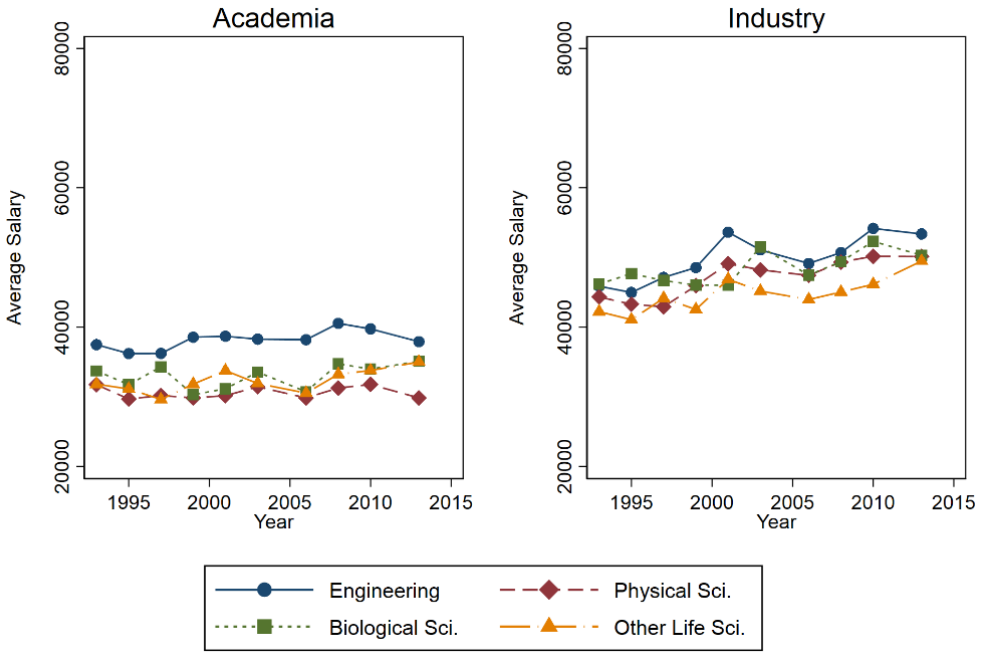

Notes: Figure B.3 shows the average work hours and salary for biomedical doctorates age 28-32 employed as postdocs in the given year compared to biomedical doctorates of the same age employed in industry in the same year. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year. Salary adjusted for inflation using the CPI-U with base years 1982-84.

Figure B.4: Share of Biomedical Doctorates Working in Each Employment Sector

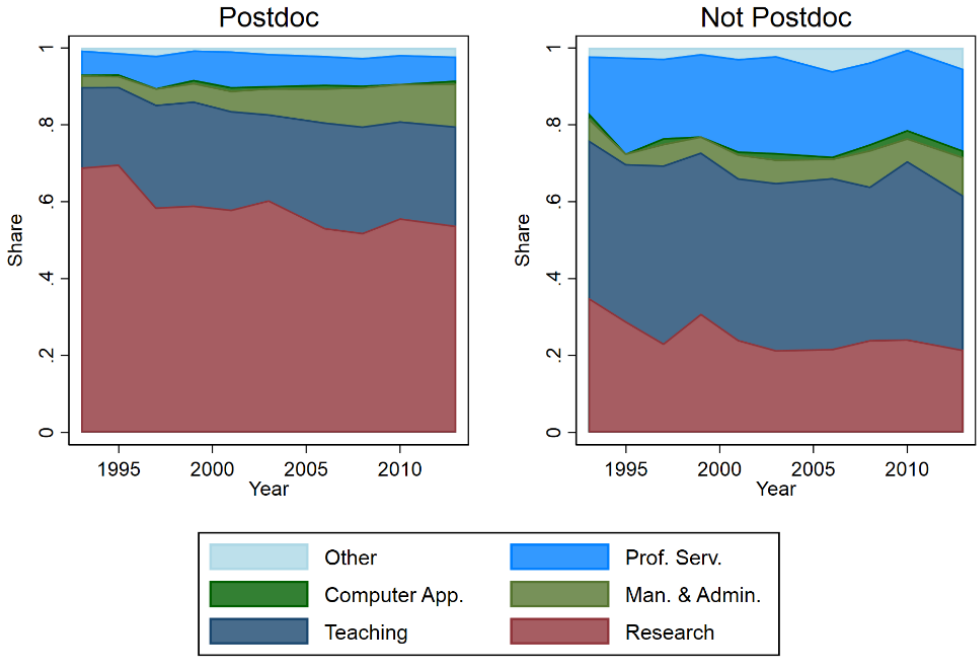

Notes: Figure B.4 shows the share of biomedical doctorates age 30 to 40 working in each employment sector by year and whether they have postdoc training. "Government" sector includes both government and nonprofits. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.5: Average Salary by Employment Sector and S&E Field

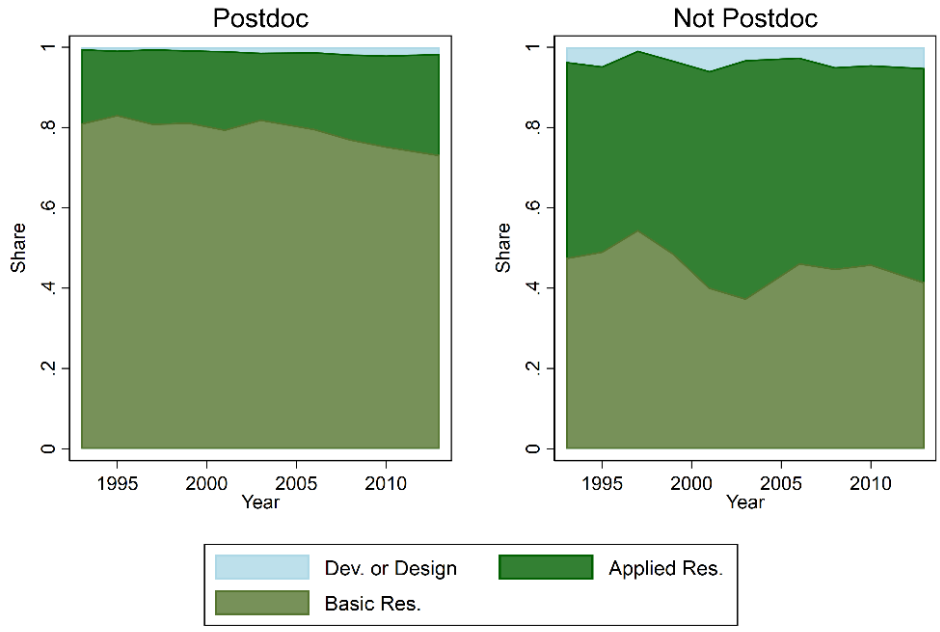

Notes: Figure B.5 shows the average salary of doctorates age 30 to 40 working in each employment sector by year and broad field of study. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year. Salary adjusted for inflation using the CPI-U with base years 1982-84.

Figure B.6: Share of Biomedical Doctorates in Academia by Primary Work Activity

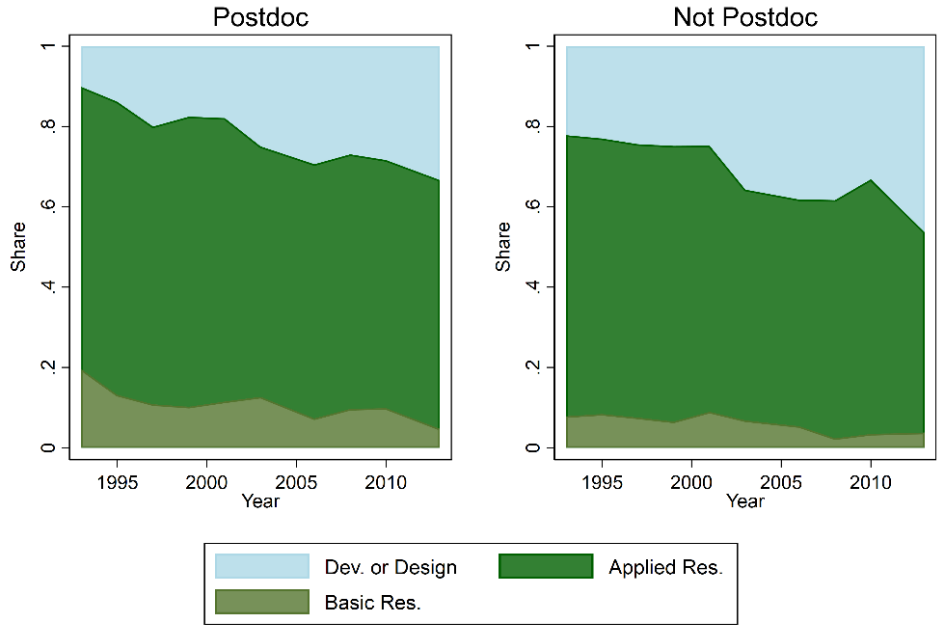

Notes: Figure B.6 shows the share of academia-employed biomedical doctorates age 30 to 40 in different reported primary job tasks by year and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.7: Share of Biomedical Doctorates in Academic Research Jobs by Primary Research Activity

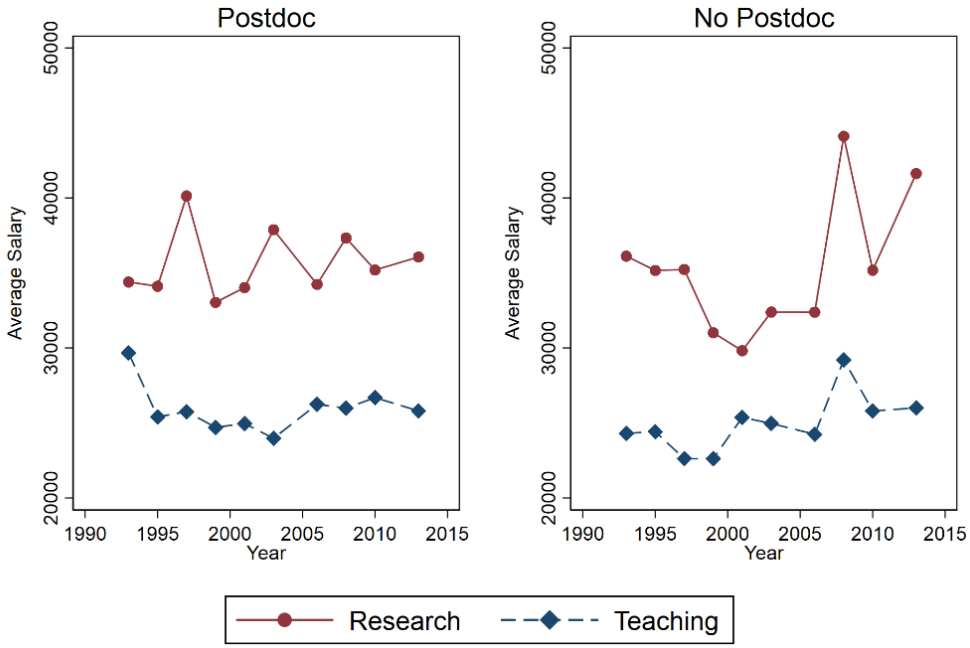

Notes: Figure B.7 shows the share of biomedical doctorates age 30 to 40 who are employed in academic research jobs broken down by the different types of research activities and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.8: Share of Biomedical Doctorates in Industry Research Jobs by Primary Research Activity

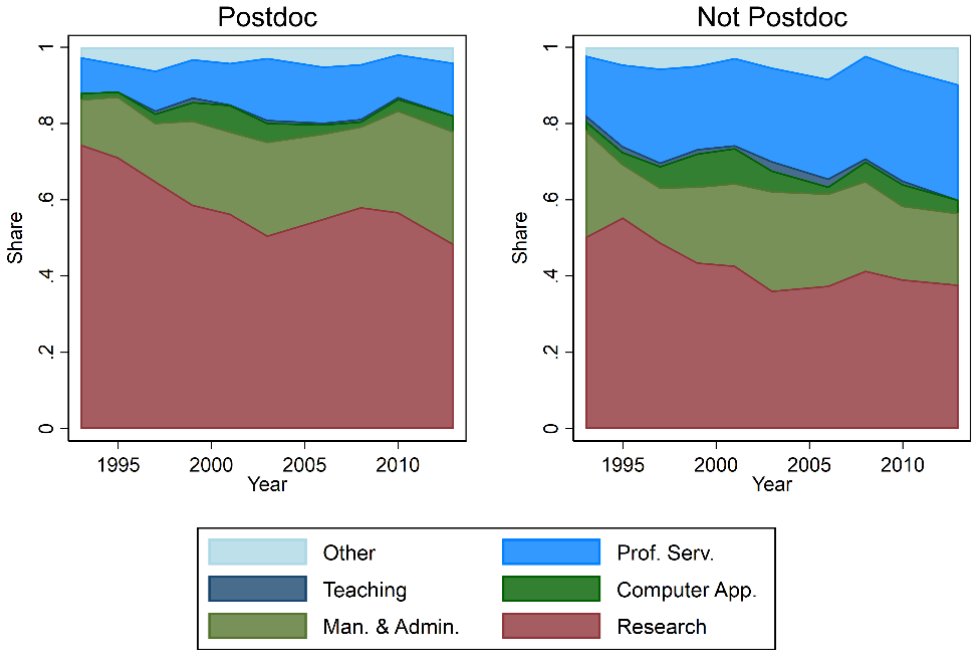

Notes: Figure B.8 shows the share of biomedical doctorates age 30 to 40 who are employed in industry research jobs broken down by the different types of research activities and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.9: Average Salary of Biomedical Doctorates in Academia

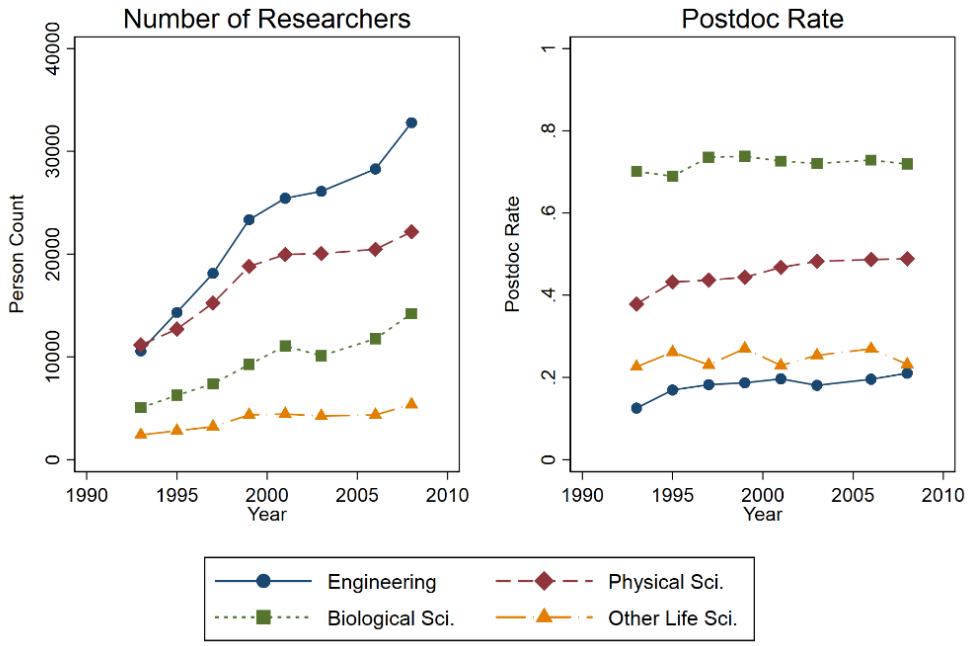

Notes: Figure B.9 shows the average salary of doctorates age 30 to 40 working in research and teaching jobs in academia by year and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year. Salary adjusted for inflation using the CPI-U with base years 1982-84.

Figure B.10: Share of Biomedical Doctorates in Industry by Primary Work Activity

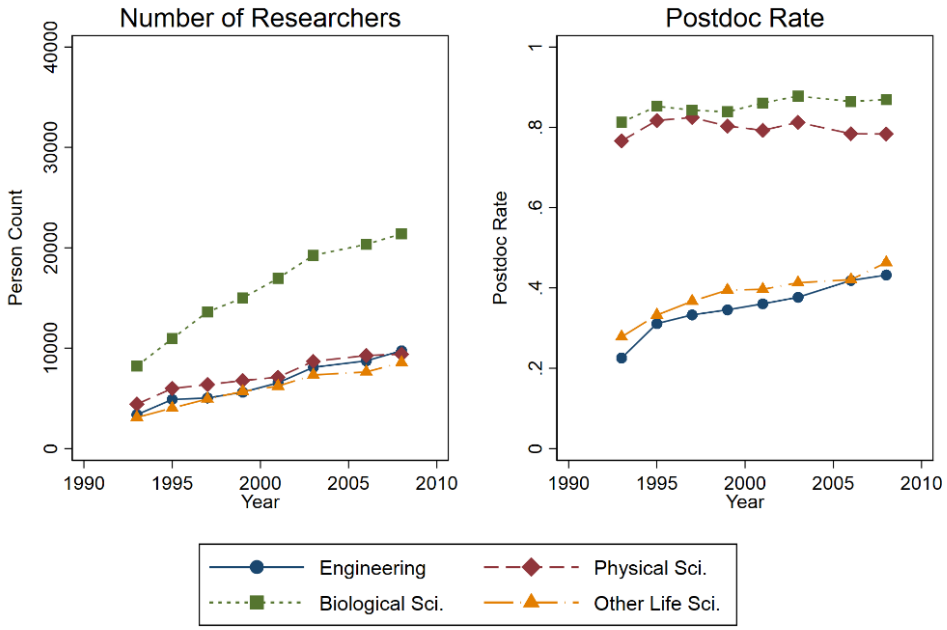

Notes: Figure B.10 shows the share of industry-employed biomedical doctorates age 30 to 40 in different reported primary job tasks by year and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.11: Number and Postdoc Rate of Industry Researchers by S&E Field

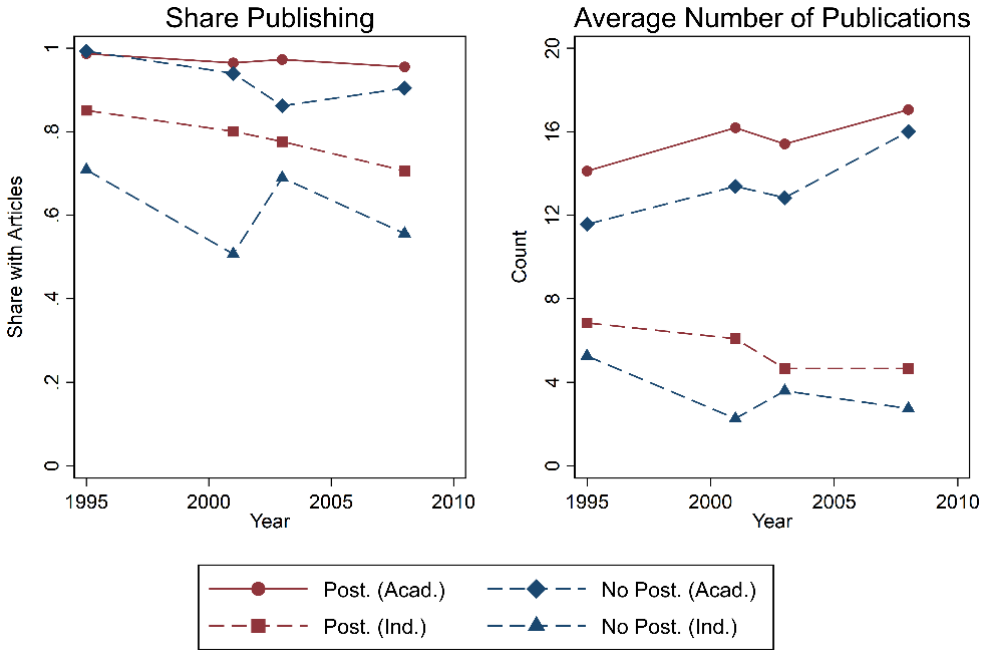

Notes: Figure B.11 shows the number and postdoc rate of doctorates working in research jobs in industry by year and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.12: Number and Postdoc Rate of Academic Researchers by S&E Field

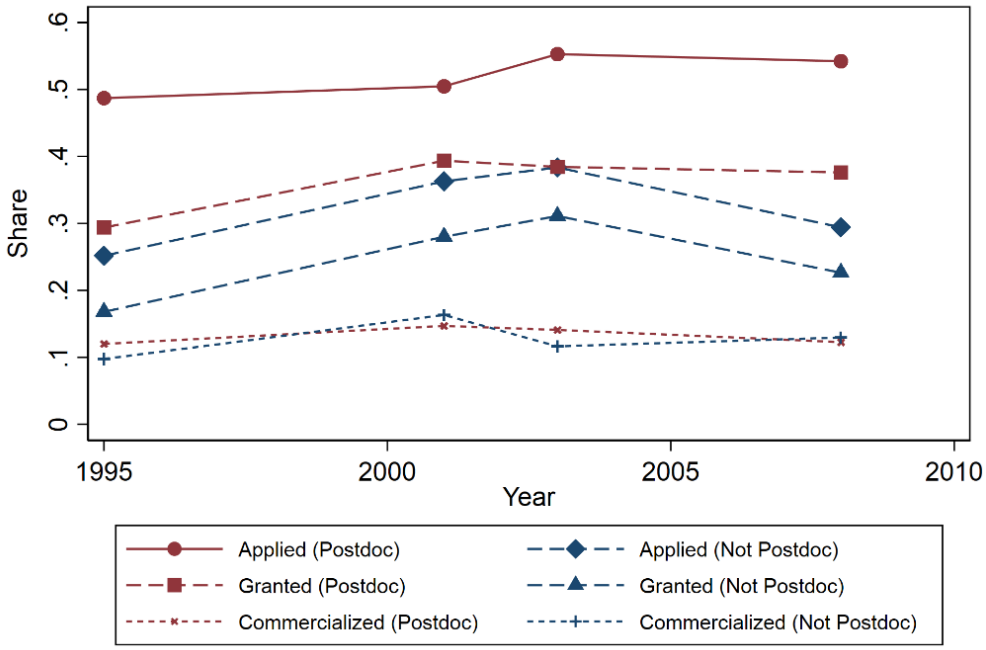

Notes: Figure B.12 shows the number and postdoc rate of doctorates working in research jobs in academia by year and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.13: Publishing Activity by Employment Sector and Prior Postdoc Status

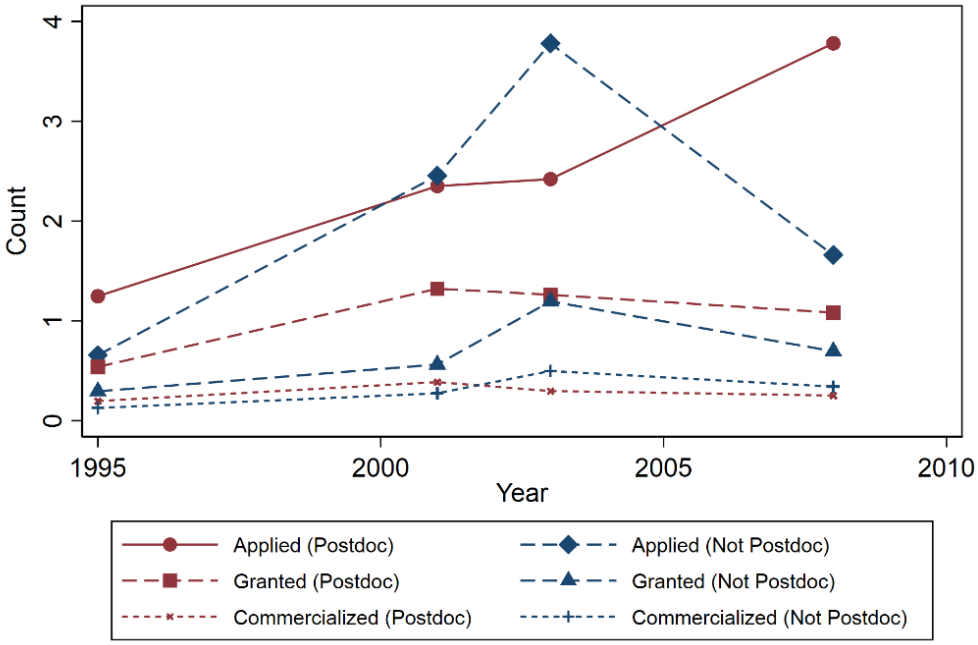

Notes: Figure B.13 shows the share of biomedical doctorates age 30 to 55 with peer-reviewed publications in the five years preceding the given SDR wave, and shows the average number of peer-reviewed publications in the last 5 years, by SDR survey wave and whether they have postdoc training. Require that individuals had finished postdoc seven or more years prior to survey wave or had graduated with a PhD seven or more years prior if did not do a postdoc; this restriction is so that we avoid counting papers authored during a postdoc or graduate school. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.14: Share of Industry Biomedical Doctorates by Patenting Activity

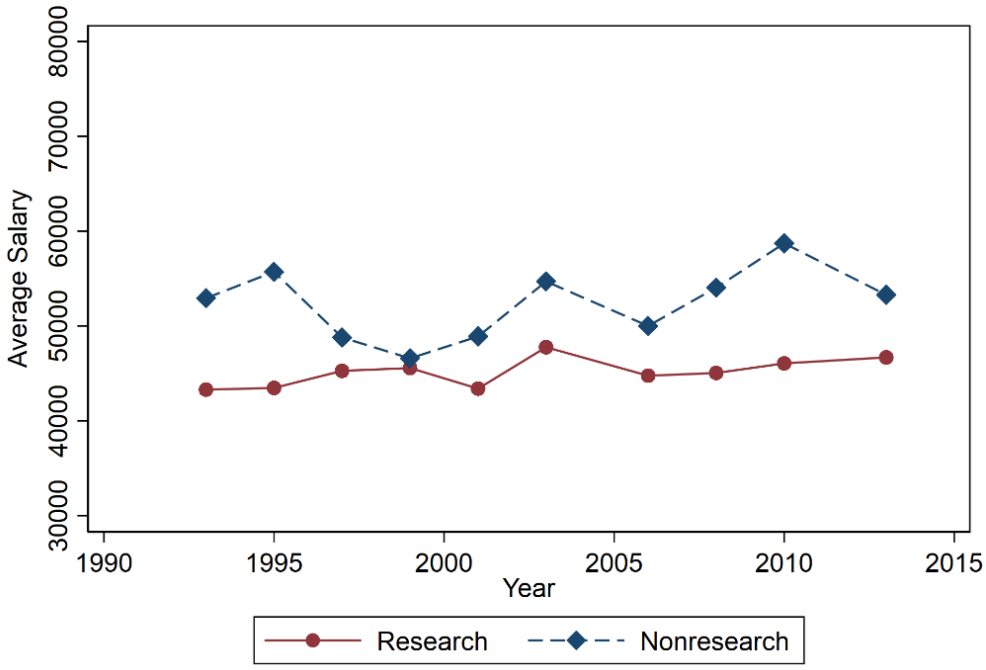

Notes: Figure B.14 shows the share of industry-employed biomedical doctorates age 30 to 55 named as an inventor on a patent application, granted patent, and/or granted patent that resulted in a commercial product in the five years preceding the given SDR by whether they have postdoc training. Require that individuals had finished postdoc seven or more years prior to survey wave or had graduated with a PhD seven or more years prior if did not do a postdoc; this restriction is so that we avoid counting patents resulting from research conducted as a postdoc or graduate school. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.15: Average Number of Patents per Industry Biomedical Doctorate

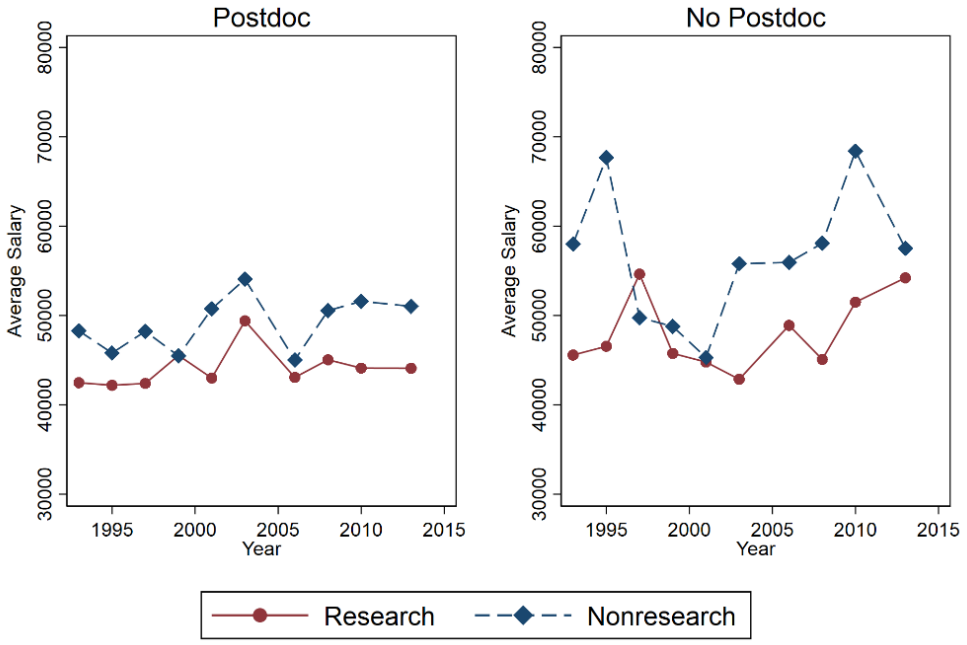

Notes: Figure B.15 shows the average number of patent applications, granted patents, and/or granted patents that resulted in a commercial product in the five years preceding the given SDR for industry-employed biomedical doctorates age 30 to 55 by whether they have postdoc training. Require that individuals had finished postdoc seven or more years prior to survey wave or had graduated with a PhD seven or more years prior if did not do a postdoc; this restriction is so that we avoid counting patents resulting from research conducted as a postdoc or graduate school. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.16: Average Salary of Biomedical Doctorates in Industry by Job Type

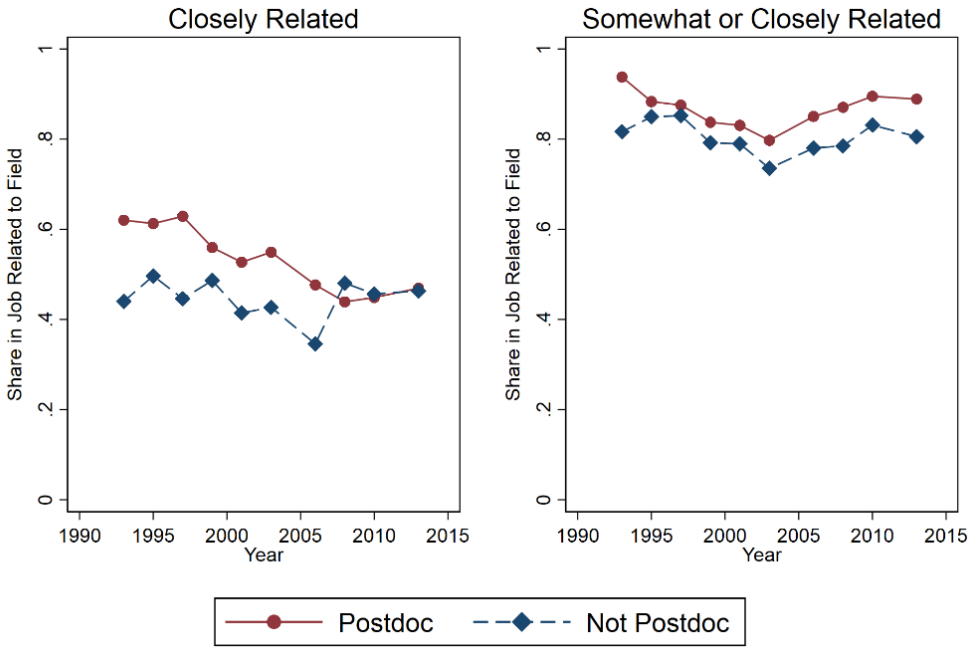

Notes: Figure B.16 shows the average salary of biomedical doctorates age 30 to 40 working in research and nonresearch jobs in industry by year. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year. Salary adjusted for inflation using the CPI-U with base years 1982-84.

Figure B.17: Average Salary of Biomedical Doctorates in Industry by Job Type and Prior Postdoc Status

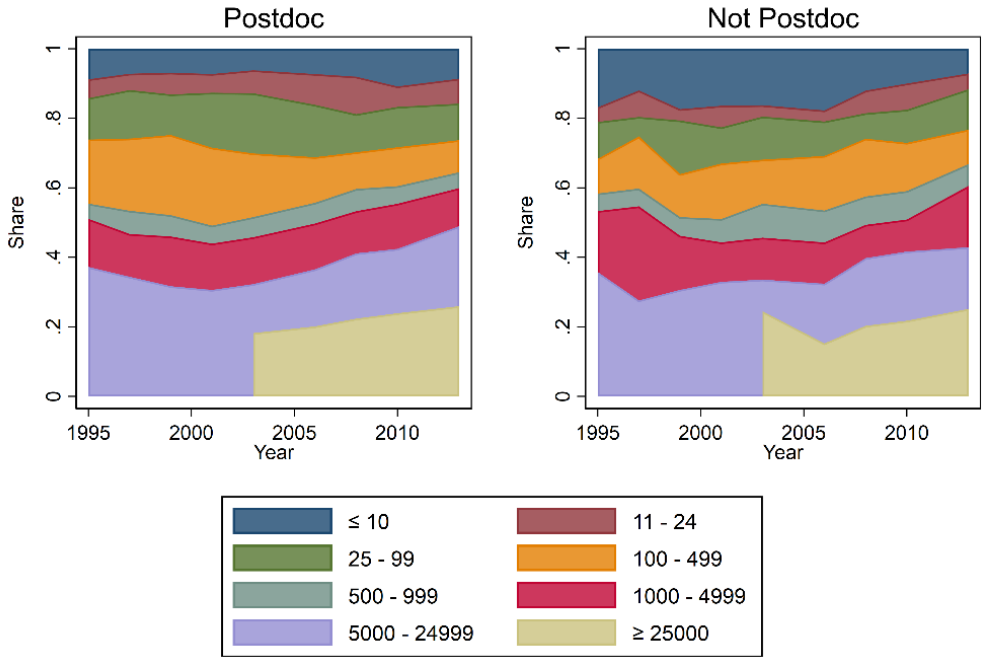

Notes: Figure B.17 shows the average salary of biomedical doctorates age 30 to 40 working in research and nonresearch jobs in industry by year and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year. Salary adjusted for inflation using the CPI-U with base years 1982-84.

Figure B.18: Share of Industry Biomedical PhDs by Job-Relatedness to Field

Notes: Figure B.18 shows proportion of industry-employed biomedical doctorates age 30 to 40 working in jobs related to their field by year and whether they have postdoc training. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.

Figure B.19: Share of Industry Biomedical PhDs by Firm Size

Notes: Figure B.19 shows proportion of industry-employed biomedical doctorates age 30 to 40 working in firms of different size by year and whether they have postdoc training. The SDR did not include a category for firms with more than 25,000 employees until 2003. Sample restricted to doctorates appearing in the NSF's Survey of Doctorate Recipients in any wave(s) between 1993 and 2015 and graduating as early as 1980. We restrict sample to doctorates who first appear in the SDR prior to 2010 due to SDR sampling changes starting in that year.
