Abstract

What explains global differences in economic prosperity? While many theories have been advanced, to date little attention has been paid to the oldest and most fundamental of human institutions: kin-based institutions—the set of social norms governing lineage, marriage, residence, and family obligations. We establish a tight empirical link between the tightness and breadth of kin-based institutions—their kinship intensity—and economic development. Combining data on satellite luminosity, regional GDP, marriage practices and kin-based institutions, biogeographic variables, and genotypic data (from which we estimate inbreeding levels), we find that lower kinship intensity tends to be associated with higher levels of economic development. Our results are robust to controlling for a suite of geographic and cultural variables and hold across countries, within country at both the regional and population (ethnicity) levels, and within country in spatial regression discontinuity analysis.

PRELIMINARY DRAFT: DO NOT CIRCULATE OR CITE

1 Introduction

Understanding the origins of global and regional differences in economic prosperity is among the oldest endeavors in economics, tracing back through Max Weber (1958) and Adam Smith (1776) to the likes of Montesquieu (1748), Machiavelli (1531) and Ibn Kaldun (1377).[1] However, in recent decades, the availability of new data sources and improved approaches to causal identification have shed fresh light on these questions, with researchers making the case for the role of a suite of important factors, including climate and geography (Diamond, 1997; Hibbs and Olsson, 2004; **?**), disease (**?**), political institutions (Acemoglu et al., 2002), colonialism (Dell, 2010), human capital (Glaeser et al., 2004), the slave trade (Nunn, 2008) and culture (Landes, 2000; Tabellini, 2010; Alesina et al., 2013; Henrich, 2020). While important roles for many factors have been demonstrated, including those based on reduced-form causal inferences from plausibly exogenous variables, the emerging picture is one of a complex causal network in which aspects of climate, geography, ecology and endemic disease (e.g., malaria) operate, at least partly, through their impact on the cultural evolution of technologies (e.g., writing), institutions (Spolaore and Wacziarg, 2013; Rodrik et al., 2004), social norms, preferences (e.g., fairness), beliefs (e.g. in particular gods) and aspects of psychology like individualism, patience and trust (Spolaore and Wacziarg, 2013; Galor and Özak, 2016; Easterly and Levine, 2016; Enke, 2019; Henrich, 2020; Schulz et al., 2019; Galor et al., 2018; Becker et al., 2020; Gorodnichenko and Roland, 2016; Barro and McCleary, 2003; Algan and Cahuc, 2013; **?**). In this paper, we aim to establish a tight empirical relationship between measures of economic prosperity, assessed using nighttime satellite luminosity and regional outputs, and the intensity of traditional kin-based institutions, proxied using both ethnographic and genetic data (Alesina and Giuliano, 2010; Alesina et al., 2013; Greif, 2006a; Ghosh et al., 2021).

Despite being the oldest and most fundamental of human institutions, most economists are unfamiliar with the complexities of kinship systems–the diversity of ways in which societies around the world and back into history have variously extended and re-enforced (or suppressed) blood and affinal ties through social norms that regulate marriage, honor codes, obligations to kinfolk, post-marital residence, inheritance, corporate ownership of land and much more ((Murdock, 1949)). In most societies, these kin-based institutions operate over generations to continuously weaves the threads of each person's most important social connections (Greif and Tabellini, 2010; Henrich, 2020; Alesina and Giuliano, 2015; Bergeron, 2020). Kin-based institutions vary along several important dimensions, but anthropologists have long highlighted the importance of kinship intensity (Walker et al., 2013): the degree to which individuals are enmeshed broad and tight kin networks that demand their loyalty prescribe much of their behavior. As we'll illustrate below, societies dominated by small, monogamous nuclear families tend to have low levels of kinship intensity while polygynous societies dominated by endogenous patrilineal clans tend to have rather high levels of kinship intensity. Practices like cousin marriage (Bittles and Black, 2010; Leutenegger et al., 2011), customary inheritance (Bahrami-Rad et al., 2021; Bau, 2021), post-marital residence Bau (2021) and polygamy (Fenske, 2015) BAU,

[1] Of course, scholars well back into Antiquity have speculated on the question. In Islamic Spain for example, during the first century of the second millennium, the scholar Said contrasted his own "civilized" society to to the "black" and "white barbarians" to his south (Africans) and north (northern Europeans), respectively (Lewis, 2001). For the "white barbarians," Said suggests that the latitude and climate might has probably left them a bit dull.

contrary to the intuitions of some, remain important throughout the world and persist (or increase) in immigrant populations.

A growing body of work suggests that differences in kinship intensity may influence economic growth through several different causal pathways through their influence on incentives, constraints, social networks and psychology: e.g., intensive kinship has already been linked to less impersonal trust, individualism, public goods provision and effective democratic governance as well as more corruption, nepotism and conformity (Moscona et al., 2020; Enke, 2019; Greif and Tabellini, 2010; Schulz et al., 2019; Henrich, 2020; Alesina and Giuliano, 2015, 2011; Acemoglu et al., 2002; Schulz et al., 2018; Bahrami-Rad et al., 2021; Edlund, 2018; Bergeron, 2020); each of these patterns has been argued to influence economic growth and/or innovation (Gorodnichenko and Roland, 2016; Algan and Cahuc, 2013). Cutting through such intricacies, we focus on establishing the reduced-form link between economic growth and kinship intensity, though we also supplement the existing set of potential mechanisms with new evidence suggesting that lower levels of kinship intensity may foster a broader division of labor and greater occupational specialization.

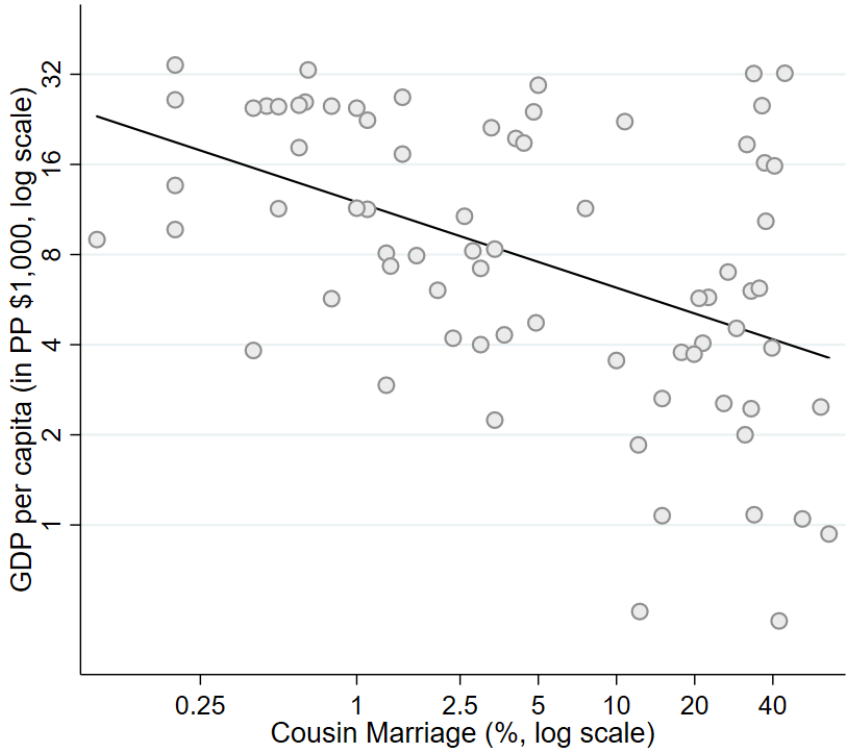

Figure 1: Per GDP capita in 2000 vs. cousin marriage prevalence across countries. Note that the dots in the upper right corner (high cousin marriage and high GDP) are all the oil rich countries: Kuweit, Bahrein, Oman, Saudi Arabia, Emirates, Quata

.

Motivating this investigation empirically: Figure 1 show the correlation between national income in 2000 (GDP per capita) and the rate of cousin marriage, a simple proxy for kinship intensity. We interrogate this relationship. To measure economic prosperity, we rely primarily on pixel-level satellite luminosity data (Michalopoulos and Papaioannou, 2013; Donaldson and Storeygard, 2016), but always hold constant populations density, thus allowing to interpret our coefficients of relationship in units of nighttime luminosity per capita. As a supplemental measure of economic prosperity, we also analyze direct

regional measures of GDP per capita (Gennaioli et al., 2014). To measure kinship intensity, we deploy an existing approach that combines data from *Ethnographic Atlas*, a compilation of anthropological observations based on coding ethnographies from over 1,200 societies, and global language phylogenies from over 7,000 ethno-linguist communities (Schulz et al., 2019; Enke, 2019; Giuliano and Nunn, 2018; Bahrami-Rad et al., 2021; Kirby et al., 2016). To verify the quality of this anthropological measure, we estimated inbreeding coefficients using the genetic data available in the Human Origins Dataset. This new measure, which captures cousin marriages and other endogamous mating practices, robustly correlates with our ethnographic measure of kinship intensity and similarly predicts economic prosperity. This relationship not only confirms the ground truth of our anthropological measure, but also implies that these observations capture enduring and important social practices–important enough to alter the genome. To test for robustness, we present an extensive battery of OLS regressions, which include country fixed effects and control for a rich range of geographic, demographic, ecological and economic control variable. In addition, we apply a regression-discontinuity (RD) analysis to the boundaries between ethno-linguistic groups, following Michalopoulos and Papaioannou (2013) and Moscona et al. (2020). Our results strongly support a robust negative correlation between kinship intensity and economic prosperity.

This paper builds on, and contributes to, a number of interrelated lines of research within economics. First, our demonstration of a robust link between kinship intensity and economic prosperity contributes to the central questions in economic history related to the origins of industrial revolution and the "rise of the West" (Mokyr, 2016; Clark, 2007). Greif and Tabellini, along with many historians and anthropologists, have argued that the transformation of European kinship into what has been dubbed the "European Marriage" (Hajnal, 1982), a virtually unique form of family organization built around monogamous nuclear family households, was central to emergence of the political and economics institutions that underpinned the European expansion after 1500 and eventually the industrial revolution (Tabellini, 2010; Greif, 2006b,a; Mitterauer, 2010; Goody, 1983; Henrich, 2020). The authors demonstrate a correlation between urbanization in 1600 and a measure of traditional family organization. Most recently, Ghosh et al. (2021) take advantage of the checkered state-level imposition of laws prohibiting cousin marriage in the United States. Their analysis shows that declines in cousin marriage precipitated by the new laws fostered urbanization and economic growth in the 20th centuries. Our results extent these insights into the modern era and around the globe.

Second, in a closely related literature, there's the question of how to explain contemporary differences in economic prosperity. By revealing a robust, and potentially causal, relationship between kinship intensity and economic prosperity, we place kin-based institutions, rooted in a set of culturally transmitted social norms, into the cluster of other important institutions and cultural practices that have been linked to economic growth (Alesina and Giuliano, 2015; Nunn, 2012). Our focus on kin-based institutions can contribute to explaining the long-term persistence of economic prosperity (Comin et al., 2010; Edlund, 2018), the influence of both early European settlements (Easterly and Levine, 2016) and Christian missions (Calvi and Mantovanelli, 2016; Bai and Kung, 2015), and diffusion of innovations from the technological frontier (Spolaore and Wacziarg, 2013). There are several reasons for this. Unlike the commonly used measures of formal institutions such as constraints on the executive, kin-based institutions are generally vertically culturally-transmitted at the group-level and strikingly persistent across time: analyses from both economics and anthropology using diverse measures of kin-based institutions

demonstrate that these cultural traits are among the most persistent (Guglielmino et al., 1995; Alesina and Giuliano, 2014; Bahrami-Rad et al., 2021)—this stickiness of these institutions may contribute to the persistence of economic outcomes. Nevertheless, early European settlers would have brought their low intensity kinship norms with them, and disseminated them to other populations through some combination of coercion or persuasion. Running in parallel, Christian missions often explicitly preached against polygyny, cousin marriage, arranged marriages and other elements of intensive kinship (Fenske, 2015; Bergeron, 2020) while actively working to spread Christian supernatural beliefs. Of course, European kinship customs often made their way into the developing civil codes of non-European populations, but this occurred unevenly across space and time. Of course, many factors likely contribute to economic impacts of early European settlement and Christian missions, and the social and psychological elements that foster the flow of ideas and innovations among populations.

Finally, our analyses contribute to the growing literatures on the role of social norms, culture, historical legacies and economic development (for overviews, see Spolaore and Wacziarg, 2013; Nunn, 2010; Michalopoulos and Papaioannou, 2018), which links kin ties to (1) particular aspects of psychology, (2) the functioning of political institutions, educational investments, and (3) rates of intergroup violence, and (4) economic development (Edlund, 2018; Fafchamps, 2011; Platteau, 2000; Hoff and Sen, 2011; Henrich, 2020) Pioneering this effort, Alesina et al. (2013, 2015) have argued, using data from the World Value Survey, that the importance of close ties within the nuclear families related to female labor force participation, political attitudes, the importance of family businesses and, ultimately, economics prosperity. Complementing this work, Akbari et al. (2019) provide evidence that higher cousin marriage rates are associated with higher frequency of corruption across countries and also across European regions. In the Democratic Republic of Congo, using the historical locations of Christian missions, Bergeron (2020) shows that city dwellers whose home villages were closer to historical missions revealed greater moral universalism and reported social networks with more people outside their families and ethno-linguistic groups. Using global data, both Enke (2019) and Schulz et al. (2019) demonstrate a robust correlation between between kinship intensity or 'tightness' and measures of impersonal trust, moral universalism, conformity, analytical thinking, individualism and cooperation with strangers.

While central to our focus on economic growth, some work has linked various aspects of kin-based institutions to important outcomes, which likely have direct or indirect links to economic performance. First, testing venerable ideas from anthropology on the origins of honor cultures (Sahlins, 1961), (Moscona et al., 2017, 2020) show that segmentary lineage organizations in Africa appear link to both less trust in strangers and more intergroup violence. In Indonesia and Ghana, Bau (2021) shows that traditional norms about post-marital residence—patrilocality or matrilocality—interact with the arrival of pension systems to influence the education of either males or females. Bau's investigation also show how pension systems undercut one of the primary function of intensive kinship, resulting in the decline of traditional kinship practices. Similarly, focusing also on the differential impact of different kin-based institution in the Democratic Republic of Congo, Lowes 2018 shows experimentally that matrilineal wives are less cooperative with their spouses than patrilineal wives—as long suggested by anthropologists—but they experience less domestic violence and their children are healthier and better educated. Finally, looking both historically within Europe and cross-nationally today, van Zanden et al. (2019); de Moor and van Zanden (2010) and Carmichael and Rijpma (2017), re-

spectively, investigate the effect of family systems on women's agency and labor market participation.

The paper is organized as follows. In section 2, we discuss the most important components of kin-based institutions and provide two measures of kinship intensity: one based on anthropological literature, and the other from population genetic data. To illustrate how kinship intensity shapes societies, we take a closer look at three societies with varying degrees of kinship intensity. In section 3, we describe our measures of economic prosperity (nightlight luminosity density and regional GDP per capita) and our control variables. In section 4, we present our regression analyses of the association between kinship intensity and economic development. This also includes a spatial regression discontinuity analysis. Section 5 focuses on the estimates using the inbreeding coefficient. We provide evidence that inbreeding coefficient is highly correlated with our other kinship intensity measure and has a significant association with luminosity per capita. In section 6, we explore potential mechanisms behind the association of kinship intensity and economic development. Section 7 concludes the paper.

2 Kin-based institutions

Our primary focus is on establishing a tight empirical relationship between the tightness and breadth of kin-based institutions—captured by their *kinship intensity*—and economic prosperity. In this section, we'll develop the concepts of kin-based institutions and kinship intensity and then outline how we measure kinship intensity. In our subsequent Data section, we'll explain how we measure economic prosperity and describe our battery of control variables.

Kin-based institutions are the package of social norms that govern marriage and relationships with the family and community, and include norms related to inheritance customs (e.g., matrilineal), polygamy, kin marriage, clans, household organization and post-marital residence (e.g., patrilocality), among other. Anchored in well-established aspects of human nature (Henrich, 2016), such as incest avoidance, kin-based institutions represent the oldest and most fundamental of human institutions (Murdock, 1949; Parkin, 1997). Over the course of human history, and well back into our evolutionary past, they usually played a central role in organizing economic production, distribution, consumption, political decision-making and social insurance (for injury and in old age).

Kin-based institutions are quite variable across human societies, having evolved culturally in response to diverse ecologies, novel technologies, new religious beliefs, and state policies (Dalton and Leung, 2014; Daynes, 2001; Fenske, 2015; Henrich, 2020; Schulz et al., 2019; Bau and Fernández, 2021). Today, for example, roughly 1.1 billion people in Africa, the Middle East and parts of Asia reside in regions in which between 20 to 50 percent of marriages are between second cousins or closer kin (Romeo and Bittles, 2014), and many populations still trace descent primarily through either the male line or the female line (Moscona et al., 2020). This contrasts with Western societies, where social structure is characterized by a strong emphasis on the monogamous nuclear family, kin marriages are virtually absent, and descent is bilaterally traced through both the mother's and the father's side (Greif, 2006a; Goody, 1983; Mitterauer, 2010).

In considering how kinship shapes people's lives, minds and society, anthropologists have characterized cross-societal variation in kin-based institutions along the dimension of extensive vs. intensive kinship systems (Walker et al., 2013; Walker and Hill, 2014;

Henrich, 2020; Schulz et al., 2019). Intensive kinship norms foster tight, dense and overlapping relationships, which often create essentialized 'corporate groups' such as clans that are much less closely connected to other such groups (Enke 2019 calls this "kinship tightness"). Cousin marriage, for example, weaves families together into dense kin-based networks, which provide preferred relationships for economic exchange, mutual aid, insurance and political alliances. Cousins, of course, are already kinfolk but cousin marriage re-enforces these bonds with additional ties, and perhaps more importantly, helps guarantee that these relationships endure in later generations. Similarly, growing up in extended families or clans where several related families reside in the same dwelling or community, respectively, tightens cohesion within groups of kin. Norms that establish unilineal descent, prescribe post-marital residence, favor arranged marriage, and encourage polgynyous arrangements all also intensify kinship.

By contrast, extensive kinship systems such as those found among mobile hunter-gather populations, are characterized by marriage to non-kin (often based on incest taboos that prohibit cousin marriage), bilateral descent rules, an emphasize on the nuclear family, and flexible residence norms. Marrying and residing with non-kin creates large and more diverse kin networks, as does bilateral descent, where people trace relatedness trough both the mother's and the father's side. This creates large, interconnected, and non-exclusive kin networks in which everyone except siblings has a unique combination of relatives.

2.1 Measuring kinship intensity

Our analyses rely on two main measures of the degree of kinship intensity that characterizes a society. The first measure, which we use in most of our analyses, is the Kinship Intensity Indicator (KII) from (Schulz et al., 2019). The KII is an omnibus measure of the overall strength of kin-based institutions constructed using anthropological data and available for over 1,000 societies. To complement this anthropological measure and verify the robustness of our main results to using a contemporaneous, on-the-ground measure of kinship intensity, we use the inbreeding coefficient measured from genetic data from the Human Origins (HO) dataset, available for a few hundred societies.

The Kinship Intensity Index (KII)

The Kinship Intensity Index (KII), which we developed in previous work (Schulz et al., 2019)[2], is constructed using observations from an enhanced version of the Ethnographic Atlas (EA) (Murdock, 1967) obtained from the Database of Places, Language, Culture, and Environment (DPLACE Kirby et al. (2016)). The EA quantifies anthropological observations on 1,291 societies from ethnographies written by anthropologists prior to industrialization, with the average observation occurring around 1900 CE.[3] The KII is thus a "deep" historical measure that aims to capture enduring norms and practices before modernization, a claim we verify below using genetic data.

The KII aggregates five sub-indicators that capture key dimensions of kin-based organization:

1. *Cousin marriage preference* captures the intensity of the norms about marrying cousins. Preference for cousin marriage inhibits the formation of extensive ties

[2]We use the exactly same definitions and methodology to create KII (see (Schulz et al., 2019) for more details). But we use the newer updated versions of the Ethnographic Atlas, Ethnologue, and Glottolog.

[3]8 of the 1,291 societies were coded based on pre-1500 CE observations; we excluded them from our analyses.

among previously unconnected families or clans, encourages the creation of additional links among already related families and households, and increases the genetic relatedness of family members.

2. *Polygynous marriage norms* permit men to marry multiple wives. This results in larger and more extended households and introduces social and economic interdependence among co-wives and half-siblings. At a societal level, polygynous marriage norms result in fewer fathers, larger reproductive skews and greater genetic relatedness.

3. *Co-residence of extended families* captures the degree to which several generations of a family, each with their own spouses and children, co-reside. Such residential norms create stronger emotional bonds and greater economic interdependence among the co-residing individuals. This contrasts with the neolocal nuclear family, where only the two spouses with their children live together, separate from other relatives.

4. *Lineage organization* captures rules of descent. In unilineal societies descent is traced either through the mother's or the father's side; the exclusive membership on one side determines social identity and increases cohesion and interdependence within the lineage. This contrasts with bilateral descent where membership is non-exclusive and everyone except siblings have a unique combination of relatives, resulting in more diverse and diffuse kin-networks and lower kinship intensity.

5. *Community organization* captures whether extended family and clan members reside within the same localized area (e.g., neighborhood) of a settlement, and whether there is community-level endogamy (e.g., people can only marry co-villagers). Localization decreases the interaction with outsiders while endogamous communities form denser clusters (since no outsiders from different villages join the community through marriage), thereby increasing kinship intensity.

As we further describe in the next section, we matched the EA data (including the KII sub-indicators) to ethnolinguistic from the Ethnologue (Gordon, 2005; Lewis, 2009), a comprehensive map of the world's languages. We used two alternative matching methods to do so: the language-tree matching method and the direct-matching method. When using the language-tree matching method, we imputed missing observations for cousin marriage preference and co-residence of extended families sub-indicators.[4]

To compute the KII for each ethnicity, we first standardized the five sub-indicators using their means and standard deviations across the EA societies; then, we took the average of the ethnicity's five matched sub-indicators and standardized that average using its mean and standard deviation computed across the EA societies. The resulting KII is defined for the Ethnologue's ethnolinguistic but is standardized based on the EA societies.[5] Figure 2 shows the distribution of the KII across the national ethnicities around

[4]To do this, we follow Schulz et al. (2019). Specifically, we imputed missing observations for cousin marriage preference sub-indicator using data on cousin term. The co-residence of extended families sub-indicator includes two components: extended family and marital residence locality. We imputed each component of co-residence of extended families sub-indicator using the other component. See Schulz et al. (2019) for more details on variables.

[5]We standardized the sub-indicators and the KII based on their means and standard deviations across the EA societies, rather than across the Ethnologue ethnicities, because the different matching methods we use lead to different subsets of ethnicities being matched to the EA, and some of these ethnicities

the world, and Appendix A.1 provides further details on the construction of the five sub-indicators and of the KII.

Although Schulz et al. (2019) selected the five sub-indicators on purely theoretical grounds—aiming to operationalize the anthropologists' concept of kinship intensity—these measures turn out to be highly intercorrelated across the EA societies with non-missing data (see Appendix Table B.1.1).

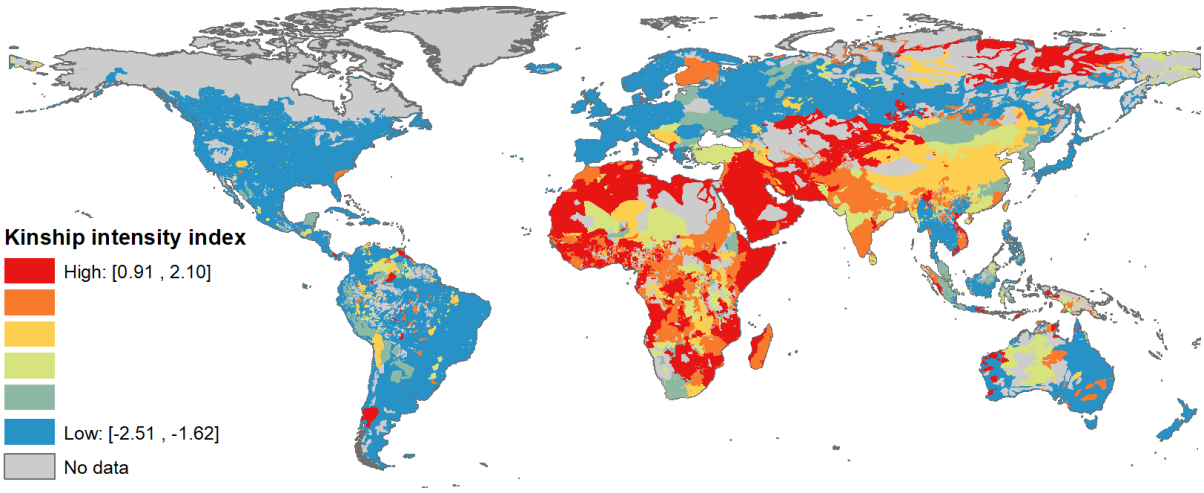

Figure 2: Distribution of the KII around the world, for the 2,352 ethnicities matched with the language-tree matching method (described below).

The inbreeding coefficient (F)

Our second measure of kinship intensity, the inbreeding coefficient (denoted F), is a key variable in the field of population genetics that can be estimated using one's genetic data. F is an individual-level measure of the relatedness of one's parents, and so a society's average F should in principle correlate with its kinship intensity and in particular with it rate of marriage with cousins or relatives. As we describe in more detail in Section 5, we estimate F for contemporary individuals in the Human Origins (HO) dataset (Reich Lab, 2020)—a dataset of genotyped individuals from populations around the world—then estimate the mean F across the HO individuals matched to each national ethnicity from the Ethnologue.

Because the KII ultimately derives from ethnographic observations, often made over the course of a year or so of field research, one might worry that it represents merely ideal behavior (vs. ground truth of how people live their lives), or a snapshot in time of an otherwise unstable or rapidly changing pattern of kinship (Leach, 1964). Using F measured among contemporary individuals as our alternative measure of kinship intensity allows us to verify that the KII captures stable cultural practices. As we report below (see Table 6 and Appendix Table B.5.2), F is positively associated with the KII and particularly strongly associated with our cousin-marriage-preference sub-indicator, indicating that the KII does indeed capture enduring cultural practices. Consistent with this, Pemberton and Rosenberg (2014) and Sahoo et al. (2021) also report positive associations between F and cousin marriage preferences or practices.

We emphasize that, although we estimate it using genetics data, F is a *cultural* variable and its mean value in a society can in principle change substantially from generation

correspond to very small groups; standardizing based on the EA societies allows to us to consistently interpret the coefficients we estimate across our different analyses.

to generation. To the extent it captures the deep-rooted cultural practice of cousin marriage, however, it should be rather stable through time.

2.2 Kinship intensity on the ground in 3 societies

To better understand how high kinship intensity shapes societies and individuals, let's take a closer look at three societies with a high, medium and low KII and F values. Exemplifying a kinship intensive societies, the Marri Baluch are agro-pastoralists who live enmeshed in a hierarchy of patrilineages in a mountainous region Pakistan lying about midway between Islamabad and Karachi. Traditionally, the nomadic Marri Baluch have relied primarily on herding sheep and goat, though some households (particularly elites) maintain mud houses in villages and engage in cereal farming, mostly growing wheat. The ownership of both land and animals is communal, though animals can be individually owned, and both forms of wealth are transferred communally by the inheriance of a Marri identity from one's father (but he has no say on this). All pasture land is held in common (among Marris) while agricultural land is reapportioned every decade or so among large patrilineal groups according to the number of Marri men in each. Interestingly, although paternal kinship is the central factor in economic, political and social life, getting 'counted' for land apportionment depends also on not having a mother is low-caste or a slave. Marriages are typically arranged for adolescent girls, who are 'sold' by their fathers for a brideprice (e.g., 80 sheep) to other men. There's a strong preferences for marriages with the same small patrilineage (*wari*), a preference reflected in the lower brideprices associated with marriages. In one survey, 30 percent of marriages between patrilateral parallel cousins—i.e., the children of two brothers—and a third were among patrilateral relatives. In total, 72 percent of marriage were among kin while no marriages occurred outside of the Marri Baluck. Compared to most high kinship intensity societies, incest taboo are not particularly constraining: beyond primary female relatives, men are tabooed from having sex with the wives of their fathers, father's brothers, brothers, sons and brothers' sons. Polygynous marriage is permitted, up to four wives following Islamic law, though the relative equality among most men means that this largely limited to political elites, whose positions often depend on paternal succession. Only 5 percent Marri households were polygynous at any one time. Curiously, inherited political offices among the Marri have no customary power to tax except for the purposes of paying brideprices for wives. Post-martial residence was strongly patrilocal, so wives move to live their husband's family. Women are essentially owned and controlled by either their fathers or husbands. Economically, labor is primarily organized along kinship lines, with a division of labor by age and sex. Locally, decision-making power is vested according to age and lineage position, so fathers dictate to sons, and elder brothers to younger brothers. The ability of household to protect their domesticated animals and women from theft and kidnapping depends on the honor and reputation (for revenge) of the patrilineage. The honor and shame of men in the same patrileage is intertwined, so a son who acts cowardly stains the honor of his father and brothers (and other agnates to a diminishing degree).

The package of social norms create substantial economic, social and political interdependence among relatives, especially close patrilineal men, also put them into zero-sum competitions for farmland, pasture and mates. Several customs help to bind the small patrilineages together that form the core of economic life and security. For example, the extended incest taboos, by applying to precisely the men with whom a man might live together with in a nomadic, they reduce sexual competition and mitigate concerns that

men have about their wives engaging in adulterous affairs (which are rampant). Similarly, unlike many societies with cousin marriage, the preference for endogenous unions within the patriline effectively tightens the bonds within the *wari*, though at the same time it forgoes an opportunity to forge marital alliances with other patrilineages or beyond. The combination of incest taboos and patrilineal endogamous marriage further reduces sexual competition within the wari and residential camps because it creates a situation in which all women are tabooed for all men except for their wives. Such a situation is particular important in the nomadic herding context where men often leave their households for weeks at a time for herding, trading, raiding and wage labor.

These kin-institutions create a tight circle of trust and sense of obligation that decline rapidly outside the emphwari and residential camp. Close matrilineal and affinal ties are recognized, and do matter, but they carry none of the sense of closeness or 'duty' found in patrilineal relationships. The divisions created by kinship norms are reflected in frequent contrasts between "jind" ("one's own"), which refers to patrilineal relatives (*wari*), "*Azziz*," which captures "kinfolk" (including in-laws), and "seyyal", referring to strangers of equal status (e.g., the Pashtun or even unrelated Marri). To get a sense of how people think about these different categories, consider the comments on affines: "When you become affinally related to someone, then it is God's command not to do badness or rottenness to them. If they are strangers [seyyal], then there is no duty, it does not matter if you steal or fight. But when they become affines, then there is law....There are really no definite duties. But if you are going to do meritorious acts to someone, then you should do it to your affines." In moving camps, one Marri remarked, "Now on where we are going there will be many camps, many Marris..If they are kinsfolk (azziz), then it is good; if they are strangers (seyyal), then it is bad..."

Distrust of strangers pervades many Marris economic interactions. Inevitably, managing a farming and herding in small camps will create labor shortages. To deal with this, Marris The Marris avoidance of interactions with strangers can also be seen in how they deal with labor shortages in their camps. To hire a shepherd, a man first to his poorer patilineal relatives, next to the matrilineal relatives, and finally to his affines. Having exhausted these sources, he reluctantly turns to strangers, but anticipates problems. One man explained that, "I usually give a shepherd three chances—on theft, lying, etc, and then send him away. For adultery, however, he goes immediately." Of 35 shepherds in 5 camps, only 3 were unrelated to the owners. Similarly, when conducting trading, Marri men rely on a network of *bradirs* as they move among camps, villages and towns. Bradirs represent an institutionalized friendship of sorts and provides primary trading partners, hosts and sources of information. Crucially, *bradirs* are inherited from father to son. Men report not trading in places where they lack bradirs.

By comparison, the kin-based institutions of the Kurukh or Oraon communities of the Nagpur Plateau (northeastern India) are similar in important ways, but the norms governing life have been weakened or replaced by non-kin-based institutions. Like Marri Baluch, the Kurukh are patrilineal and patrilocal (brides move to live with their husbands), marriages are arranged, and men maintain patriarchal authority over their wives and children. Traditionally, the Kurukh were organized in patri-clans, but since moving from nomadic pastoralism into settled agriculture, including sustained contact with Hindu communities, Kurukh clans operate primarily of exogamous marriage units—it's incest to marry someone from the same clan. Notably, such clan exogamy is the opposite of the tight clan endogamy preferred by the Marri Baluch. In addition to clan exogamy, the Kurukh also taboo sex or marriage among couples known to be related within three

generations—so, anyone who shares a great grandparent (second cousins are taboo, but not third cousins). However, ethnographic data suggest that families posses rather short genealogical memories so some second cousin marriages do occur. Both polygynous marriage and communal property were probably important among the herding and hunting ancestors of the Kurukh, but monogamous marriage and privately owned land became universal among these agriculturalists.

Kurukh also possess institutions and public rituals for establishing formal, life-long, friendships. Like the Marri Baluch, Kurukh new wives arrive from other communities and move into their husband's villages, where they become part of his clan. Usually, these young women do not know anyone in their new home since wives arrive from many villages. However, unlike the Marri Baluch, have rituals that nurture a set of kin-like relationship among women. For example, approximately every three, the word goes out from the female elders for every woman should select a *sahia* or special village friend, from among the other married women in the village. Women may renew a prior *sahia* or add to their social network. At a communal ceremony, the ritual friends publically greet each other, and begin a series of ritualized and reciprocal exchanges of gifts, food, conversation and fellowship, including a visit to the goddess Devi. The sacred friendship establishes life-long bonds that link not just to the two wives, but also their entire (often unrelated) families.

Further, the Kurukh share their villages with other ethnic groups, including Hindus. Economically, the Kurukh depend on village norms that govern their interactions with other ethnic groups (caste), who engage in a variety of occupations that support the Kurkh's farming efforts. Disagreements among households adjudicated and villages policies set by a pluralistic and largely democratic council of elders, which include members from across the village. There is also a higher council, with representatives from many villages, that deals with inter-village issues. These councils appear to be a retrofit version of the supra-clan institution that once organized the Kurukh's ancestors, modified to draw representatives from either ethnic/caste groups or geographic locals.

Kin-based institutions play important roles in both of these societies, but among the Marri Baluch it weaves political, social and economic interdependence around a tightly bound patrilineage. Meanwhile, though the Kurukh have clans and authoritarian fathers, their incest taboos compels marriages to social distant Kurukh families and other non-kin-based social norms govern mutually beneficial economic and political interactions with both other Kurukh and non-Kurukh villagers. Obviously, neither our KII or F measures directly tap all of these complexity—such as the ritualized friendships among Kurukh wives—but when non-kin-based institution exist to support interaction, they replace or supplant elements or reproductive events that are captured by our measures. Kinship norms that encourage, for example, economic interdependence or physical security among kinfolk tend to foster kin-based community organizations, alliances fashioned by cousin marriage, or extend families in co-residence. When other non-kin-based institutions take up these functions, these practices generally deteriorate.

Both of these more intensive kin-based institutions contrast those found in European and European-descent societies, which are characterized by love-based marriages (but often with taboos on cousins) that form small, monogamous nuclear families in which new couples reside neither with the bride's or the groom's families but set a new residence. Descent is not a source of identity and is traced roughly equally through both mothers and father. With such tiny, ephemeral families, individuals must seek out voluntary groups for economic production and political activity and must necessarily build their

own network of friends and partners.

3 Data

This section describes the other data we used in our main analyses, including our measures of economic performance and our control variables. It also outlines how we matched data from various sources. Appendix A.1 provides a more detailed description of all the variables and data sources, and Appendix Tables B.2.1, B.3.1, B.4.1, B.5.1, and B.6.1 show summary statistics for all the variables.

3.1 Measuring economic performance

In most of our analyses, we rely on nighttime luminosity data from satellites to measure economic prosperity at the micro-level. Because we are interested in *per capita* levels of economic development, we control for log population density in those analyses.[6] To verify the validity of our results with the luminosity data, in some analyses we use regional GDP per capita as an alternative measure of economic performance.

Satellite nighttime luminosity data

Now commonly used in the literature, satellite nighttime luminosity data (also commonly referred to as light density data) has been shown to be a good proxy for economic development (Michalopoulos and Papaioannou, 2018; Donaldson and Storeygard, 2016). Importantly for our purposes, nighttime luminosity data is available at fine scales, which allows us to aggregate and match it to the geographic areas peopled by different ethnolinguistic groups for whom kinship intensity data is available.

Following Henderson et al. (2018), we use the 2010 Global Radiance Calibrated Nighttime Lights data.[7],[8] The raw luminosity data is presented as a grid of pixels with dimensions 30 arc-seconds ($\frac{1}{120}$ of a degree) by 30 arc-seconds, or approximately one square kilometer at the Equator.[9] We aggregate the original pixels (which we will henceforth refer to as "subpixels") to larger pixels of size 0.125 ($\frac{1}{8}$) degrees x 0.125 degrees ($\sim$ 191 square kilometers at the Equator) by taking the mean of the nighttime luminosity across the 225 original subpixels. This aggregation greatly mitigates the problem of overglow of light in a pixel due to light emanated from nearby pixels and helps mitigate concerns about spatial correlation at finer scales. This gives us a sample of 926,864 pixels around the globe.

[6] Specifically, we regress the logarithm of nighttime luminosity on the KII and log population density (and other controls). If the coefficient on log population density were unity, this would be equivalent to regressing log nighttime luminosity *per capita* on the KII (and other controls). In fact, in nearly all the regressions we report below with luminosity as the dependent variable, the estimated coefficient on log population density is close to unity. We further discuss this below in Section 4.1.

[7] These data are available online at `https://ngdc.noaa.gov/eog/dmsp.html`

[8] Other, uncalibrated versions of the data use a strong amplification to detect low levels of light, which can saturate measurement in the most brightly lit pixels such as those in large cities, leading to top coding of those pixels. The radiance-calibrated data we use combines a high-amplification regime for low-light pixels and a low-amplification regime for more brightly lit pixels, thus removing all top coding (Henderson et al., 2018).

[9] There are 3,600 arc-seconds in a degree. Pixel size varies with latitude: the higher the latitude, the larger the pixel. This will not be an issue in our analyses since the luminosity data measure the *density* of light (i.e., the light emitted from a pixel divided by the pixel's area).

Next, we apply several filters to prepare the luminosity data for our analyses. First, we drop all pixels that do not cover land within the borders of a country, and thus all pixels in large bodies of water. Some of the remaining pixels after that step are partially covered by water or permanent ice. Luminosity is recorded as zero for subpixels that fall on water or permanent ice, so we normalize the pixels' mean luminosity by dividing it by the fraction of their component subpixels that are covered by land.[10]

Second, and relatedly, night lights may appear brighter than they are over water or ice-covered areas. We largely avoid this blurring issue by dropping the pixels for which more than 25 percent of the area is covered by water or permanent ice ($\sim$ 2.5% of the remaining pixels at this stage). We also drop pixels through which a coastline passes ($\sim$ 3.5% of the remaining pixels).

Third, around 70% of the remaining pixels emit too little light and are coded as zero. Following Henderson et al. (2018), we consider this a censoring problem since the lowest nonzero values are considered noise and generally recoded to zero in the initial data processing. Assuming that all pixels emit some positive amount of light, we assign the lowest nonzero value (0.013) from across all the pixels to the pixels that are coded as zero. Since we will take the logarithm of nighttime luminosity, this step allows us to include these recoded pixels in our analyses.

Fourth, we drop pixels with zero population density ($\sim$ 9.7% of the remaining pixels) and pixels where one or more of the geographic control variables (which we include in our main specifications) are missing ($\sim$ 0.5%) .

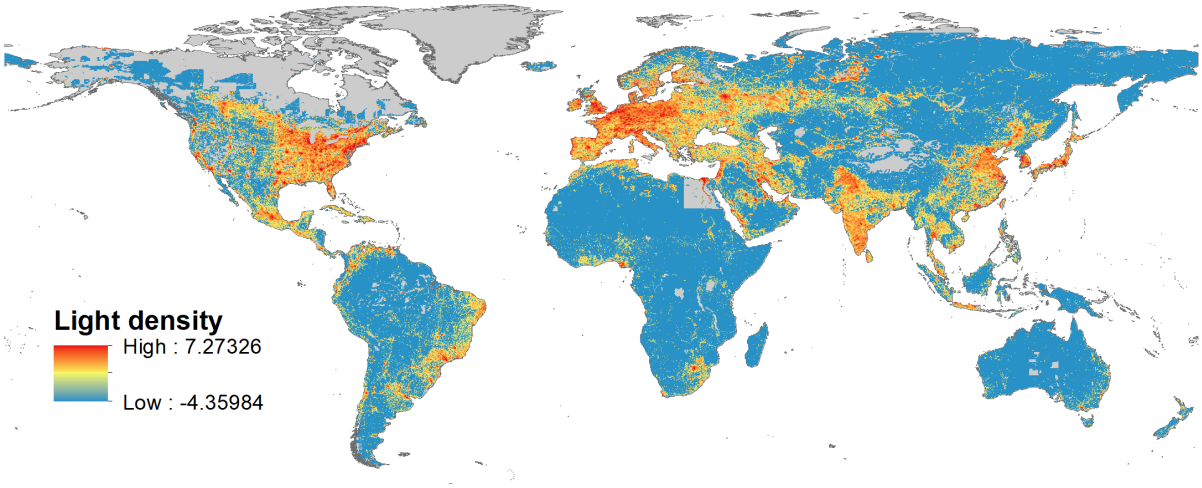

Figure 3: Distribution of log nighttime luminosity across the world. Unpopulated regions are in gray. In some areas or countries, such as Egypt, population data is available at a fine scale and unpopulated areas (like deserts) are coded as such; in other areas, population data is more heavily smoothed.

Applying these filters leaves 783,525 pixels pixels in our sample. Figure 3 displays the variation in log nighttime luminosity across these pixels around the world. Appendix Figure B.1.1 shows histograms of nighttime luminosity, but without the pixels that were recoded with the lowest nonzero value ($\sim$ 0.013). As can be seen, the log transformation reduces skewness. Therefore, and following the literature (Michalopoulos and Papaioannou, 2018), in the rest of the paper we will use the natural logarithm of nighttime luminosity.

Population data

[10]This is similar to what Henderson et al. (2018) do.

We use fine-grained population density data for the year 2010 from Gridded Population of the World (GPW), adjusted to the 2015 Revision of the United Nation's World Population Prospects (Center for International Earth Science Information Network (CIESIN) at Columbia University, 2016). GPW assumes uniform population density within statistical units. Therefore, population estimates are more heavily smoothed in countries with lower statistical capacity and in more sparsely populated regions. The GPW population density data is reported at a 30 arc-second resolution. We aggregate the data to 0.125-degree pixels by taking the mean across component subpixels, and then take the natural logarithm of population density for each pixel.

Although population density is itself often used as a proxy for economic development, our primary analyses all focus on the relationship between kinship intensity and nighttime luminosity while holding population density constant. As illustrated in Appendix Figure B.1.2, log population density has a convex relationship with log nighttime luminosity. The relationship is flat when population density is lower than 1 person per square kilometer (i.e., log(population density) < 0), but increasing and approximately linear at higher levels of population density. To avoid large variation in log(population density) driven by minor differences in population density across low-population-density pixels, we recoded to 1 the population density of all pixels whose original population density was less than 1 person per square kilometer.[11]

Regional GDP per capita data

To verify that our analyses of the association between kinship intensity and nighttime luminosity are robust to using a more direct measure of economic development, we also analyze data from Gennaioli et al. (2014) on regional per capita GDP (in Section 4.2). The data includes GDP per capita (in constant 2005 PPP dollars) for 1,528 regions in 83 countries between 1950 and 2010. We drop regions that are too small (consisting of less than five pixels) and end up with the sample of 1,452 regions. Appendix Figure B.3.1 shows the variation in per capita GDP across these regions.

Nighttime luminosity, population density, and regional GDP per capita

We conducted a simple exercise, following Henderson et al. (2018), to verify that global variation in nighttime luminosity reflects not just variation in population density, but also differences in income per capita. We aggregated our luminosity and population data to the level of subnational regions and, using the regional GDP per capita data from Gennaioli et al. (2014), regressed log nighttime luminosity on log population density and then log regional GDP per capita.[12] Without country fixed effects, the R^2's from regressing log luminosity on log population density, then on GDP per capita alone, and finally on both, are 0.55, 0.30 and 0.84, respectively. When the data are demeaned by country, the corresponding R^2's are 0.83, 0.13, 0.86. These results highlight that much of the variation in nighttime luminosity across world regions is predicted by both population density and GDP per capita; within countries, much of the variation in luminosity is predicted by variation in population density, though some residual variation is also predicted by GDP per capita.

[11] For comparison: Mongolia is the least densely populated country in the world, with 2.1 people per square km.

[12] For each region, we used GDP data for the most recent available year. Despite using a different version of the luminosity data and different population density data than Gennaioli et al. (2014), our log luminosity and log population density measures are highly correlated with theirs ($\hat{\rho} = 0.957$ and $\hat{\rho} = 0.922$ respectively).

3.2 Control variables

Throughout our analyses, we include specifications with controls for both geographic and cultural variables. Our baseline set of "geographic controls" include temperature, precipitation, agricultural suitability, absolute latitude, elevation, ruggedness, distance to coast, and distance to nearest river or lake. The raw data for these variables come from various sources and are reported at different scales ranging from $\frac{1}{120}$- to 0.5-degree pixels (see Appendix Table A.1 for details). For the variables that are defined at a smaller scale than 0.125 degree, we convert the data to 0.125-degree pixels by taking the mean across component subpixels. For variables that are defined at a larger scale than 0.125 degree, all 0.125-degree pixels that fall inside a larger pixel receive the same value.

Culturally, we verify the robustness of our results to controlling for each ethnicity's subsistence economic activities and "political hierarchies". To control for subsistence economic activities, we include a set of variables from the EA that measure the fraction of each ethnicity's subsistence economy that depends on gathering, hunting, fishing, animal husbandry, and agriculture (see Appendix A.1 for details). The EA includes five variables—one for each mode of subsistence—and we adjusted these so that they sum to 10 for each ethnicity and omitted the variable for gathering from the regressions. As discussed above, a population's mode of subsistence likely influences its KII. For instance, anthropologists have long argued that mobile hunter-gatherers culturally evolved extensive kinship as a means of social insurance against environmental shocks with low spatial autocorrelation. Ethnographically, when droughts or floods hit, foraging bands scatter and rendezvous with geographically distant relations—often in-laws or siblings—in other bands (Henrich, 2020). "Political hierarchies" is a variable from the EA that measures the number of levels of jurisdictional hierarchy for each ethnicity (Michalopoulos and Papaioannou, 2013). This variable correlates negatively with the KII ($\hat{\rho} = -0.202$, $p < 0.001$, $n = 6934$ ethnicities) and has previously been linked to nighttime luminosity, so it could confound our results.

We also verify the robustness of our results to controlling for a pixel-level measure that indexes the ecological suitability of an area for malaria (Kiszewski et al., 2004). Malaria prevalence also positively correlates with kinship intensity ($\hat{\rho} = 0.400$, $p < 0.001$, $n = 2352$ ethnicities), and may foster the cultural evolution of higher levels of kinship intensity (Enke, 2019).

3.3 Matching data

To match the various datasets whose data we analyzed, we first matched ethnographic variables from the EA (including the KII) and genetic variables from the HO dataset (including the inbreeding coefficient) to languages from the 23rd edition of the Ethnologue (Gordon, 2005; Lewis, 2009). Then, we matched the Ethnologue languages to geographic pixels and, for the analyses at the region or country level, the pixels to regions or countries.

To match the EA variables, we followed the method developed by Giuliano and Nunn (2018) and matched the language spoken by each EA society to languages in the Ethnologue (each EA society is associated with a single language). The Ethnologue maps the geographic boundaries within which each contemporary language from around the world is spoken. We refer to the (ethnolinguistic) group that speaks a given language within a given country as an "ethnicity" and to the area where the ethnicity lives as its "homeland". Thus, in our terminology, a language that is spoken in multiple countries is

associated with multiple ethnicities. The homelands of separate ethnicities often overlap, but we exclude overlapping areas from our analyses.

We employed two different matching methods. With the language-tree mapping method, we followed the methodology of Bahrami-Rad et al. (2021) and, for each EA variable and Ethnologue language, we matched the language to the linguistically closest EA society that speaks a language within the same language family and with nonmissing data for the variable. With the direct matching method, we matched the language spoken by each EA society to the exact same Ethnologue language; observations with missing data for a variable were left as missing for that variable.

For our analyses of the association between the KII on the one hand and nighttime luminosity as well as regional GDP per capita on the other, we report the analyses using the language-tree matching method in the main text and the analyses using the direct-matching method in the Appendix. For our spatial regression discontinuity analyses, we only used the direct-matching method, both to ease the computational burden and to reduce imprecision stemming from the comparison of neighboring ethnicities with imputed KII values.

For the analyses with the inbreeding coefficient, we matched each population from the Human Origins (HO) dataset to a single Ethnologue language. This is similar to the direct matching method described above for the EA data, but details of the two procedures differ because the HO data typically does not indicate the language spoken by each population. Section (Section 5 and Appendix C provide more details.

Next, we used a shapefile provided by the World Language Mapping System (World GeoDatasets)[13] to match pixels to Ethnologue ethnicities. We dropped pixels that were matched to more than one ethnicity, that fall on the boundaries of an ethnicity's polygon, or that were matched to an ethnicity with a very small polygon comprising less than five pixels. Appendix Tables B.2.1 and B.6.1 show summary statistics for the resulting samples of pixels.

Finally, to match pixel-level data to subnational regions or countries, we computed the population-weighted mean of each ethnographic variable as well as the simple mean of each geographic control across the pixels in each region or country. We then dropped regions or countries for which the pixels with nonmissing KII data accounted for less than 75% of the population. Appendix A.2 provides additional details on the matching process.

4 Kinship intensity and economic development

We now turn an examination of the association between our first measure of kinship intensity, the KII, and economic development. We first estimate a battery of regressions of nighttime luminosity on the KII (in Section 4.1) and of regional per capita GDP on the KII (in Section 4.2). We then conduct a spatial regression discontinuity (RD) analysis of the association between luminosity and the KII (in Section 4.3).

4.1 Kinship intensity and nighttime luminosity

We begin by examining the relationship between nighttime luminosity and the KII, focusing on the sample that includes the ethnicities matched with the language-tree method.

[13]The shapefile is available at worldgeodatasets.com/language

Figure 4 shows a negative relationship across Ethnologue ethnicities between the KII and the logarithm of mean nighttime luminosity (calculated across each ethnicity's pixels) after partialling out log population density ($\hat{\rho} = -0.202$, $p < 0.001$, $n = 2,352$).

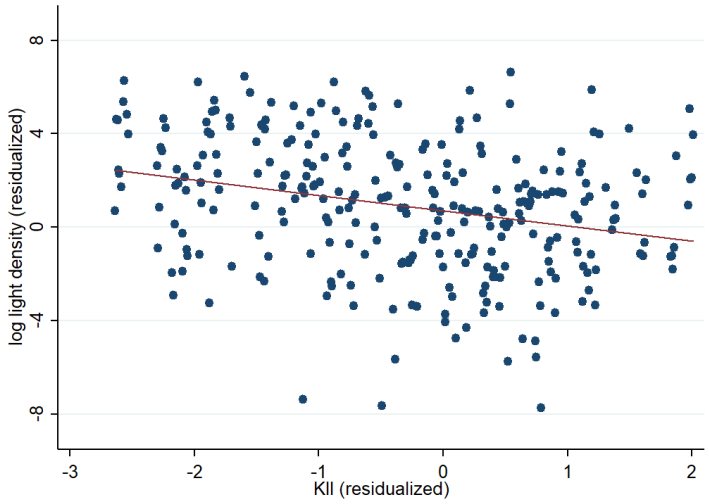

Figure 4: Log nighttime luminosity vs. the KII across ethnicities, both residualized on log population density.

To more thoroughly examine the association between luminosity and the KII, we adopted the following baseline specification, with geographic pixels as the unit of observation:

$$L_{i,e,c} = \alpha + \beta KII_e + \delta \log(P_{i,e,c}) + \gamma X_{i,e,c} + \lambda_c + \theta V_{(i),e} + \epsilon_{i,c}, \quad (1)$$

where $L_{i,e,c}$ is the natural logarithm of the nighttime luminosity of pixel i in ethnicity e's homeland in country c. KII_e is the KII of ethnicity e, which takes the same value for all the pixels in e's homeland; $P_{i,e,c}$ is the pixel's population density; $X_{i,e,c}$ is the vector of geographic variables that includes temperature, precipitation, agricultural suitability, absolute latitude, elevation, ruggedness, distance to coast, and distance to nearest river or lake; λ_c denotes continent or country fixed effects; and, $V_{(i),e}$ includes additional controls (defined at the pixel or ethnicity level, in some regressions).

As mentioned earlier, we control for log population density because we are interested in per capita levels of economic development. If we subtract $\log(P_{i,e,c})$ from both sides of equation (1) and let $\delta = 1$, the left-hand-side becomes the logarithm of luminosity per capita. We estimate δ as a free parameter to allow the luminosity-population elasticity to differ from unity (Michalopoulos and Papaioannou, 2018).[14] As it happens, our estimates of δ are close to unity in nearly all our regressions with luminosity as the dependent variables (including those in other sections reporting other types of analyses), and so we can interpret the β coefficient on the KII in equation (1) as capturing the association between the KII and the logarithm of luminosity *per capita*.

Throughout, we account for spatial correlation in the data by clustering standard errors at the country level in most specifications. We also verify the robustness of our results to clustering at the level of the language families (based on the language families

[14]Even if the true luminosity-population elasticity were unity, the population density data is noisy, so the elasticity of luminosity with *measured* population density may be lower than unity.

defined in Ethnologue) and at both the country and language family level using two-way clustering (Cameron and Miller, 2015).

Table 1: The KII and nighttime luminosity: OLS estimates

	Log nighttime luminosity								
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)

R-squared	0.462	0.530	0.570	0.653	0.653	0.654	0.654	0.653	0.653
Number of clusters	162	162	162	162	162	162	162	74	96 & 162

Notes: Each observation is a pixel in the homeland of an ethnicity matched with the language-tree method. The geographic controls include temperature, precipitation, agricultural suitability, absolute latitude, elevation, ruggedness, distance to coast, and distance to nearest river or lake. The subsistence variables measure the fraction of an ethnicity's subsistence economy that depends on hunting, fishing, animal husbandry, and agriculture (with gathering as the omitted category). Standard errors in parentheses are clustered at the country level in all regressions, except in column 8, where they are clustered at the language-family level, and in column 9, where they are clustered two-way at both the country and language-family levels. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

Table 1 reports the results of regressions that include various subsets of the covariates in equation (1). Column 1 reports a regression of log luminosity on the KII and log population density only. The KII's estimated coefficient, $\hat{\beta}$, is -0.50, indicating that a one-standard deviation increase in the KII is associated with a $\sim 39\%$ $(= (1 - e^{-0.500}) \cdot 100\%)$ decrease in luminosity, as well as in luminosity per capita. (In all columns of the table, the estimated coefficient on log population density is close to and not statistically different from unity. In column 2, when we add the geographic controls, β decreases in magnitude to -0.391. Adding continent and country fixed effects, in columns 3 and 4, reduces the magnitude of the estimates to ~ -0.10, but also decreases the standard errors, so the estimates of β remain significant. These estimates imply that a one-standard-deviation increase in the KII is associated with a $\sim 10\%$ decrease in luminosity.

In columns 5 to 7, we control for correlates of the KII that may confound its association with luminosity. In column 5, we control for each ethnicity's subsistence economic activities; in column 6, we control for "political hierarchies"; and in column 7, we control for the pixel-level malaria index. Finally, in column 8, we cluster standard errors at the language-family level, and in column 9, we use two-way clustering at both the country and language-family levels. Our results are robust to these alternative specifications.

To confirm that these results do not hinge on our use of the language-tree matching method, we re-ran the analyses reported in Table 1 using only matches from the direct-matching method. Appendix Table B.2.2 shows similar, if somewhat larger (in magnitude), estimates for β.

To examine whether these strong and consistent associations between luminosity and the KII are driven by one or a subset of the five KII sub-indicators, we estimated the specification in columns 2 (with the geographic controls) and 4 (with country fixed effects as well) of Table 1 again, but separately for each of the five sub-indicators instead of the KII as the explanatory variable. Panel A of Appendix Table B.2.3 shows the results obtained with the language-tree matching method. The associations between luminosity and the sub-indicators are all negative (except that in column 2, which is nearly 0), and the vast majority are significant at the 5% level. The results with the direct-matching method (in Panel B) are similar. Thus, most of the five dimensions of kinship intensity measured by our sub-indicators are associated with lower levels of economic development, and none is associated with higher levels. This gives us confidence in the theoretical soundness of our KII construct and in the appropriateness of aggregating the five sub-indicators into the KII to study its association with economic development.

4.2 Kinship intensity and regional GDP per capita

We now verify that the association between kinship intensity and economic development is robust to using a more direct, but less fine-grained, measure of economic development: log regional GDP per capita (mapped in Appendix Figure B.3.1). To remain consistent with the above analyses of the KII and nighttime luminosity, we estimated similar specifications, except that we included year, year-continent, or year-country fixed effects in the regressions (because of the panel nature of the data), and did not include population density (since the dependent variable is in per capita terms). As above, we clustered standard errors at the country level. We used the same set of control variables, constructed from the same data sources, and estimated one additional specification that also controls for a dummy equal to 1 if the national capital is located in the region as well as for each region's cumulative oil, gas, and liquid natural gas production from the time production began to 2000.[15]

Table 2 reports the results for the sample obtained with the language-tree matching method. In column 1, we only control for year fixed effects. The estimated coefficient on the KII is -0.491, implying that a one-standard-deviation increase in the KII is associated with a $\sim 39\%$ decrease in GDP per capita. Adding the geographical controls (in column 2) and year-continent (in column 3) or year-country (in column 4) fixed effects reduces the magnitude of the estimated coefficient on the KII, but also increases precision; as a result, the coefficient remains significant at the 1% or 5% level. The estimated coefficient in column 4, with country-year fixed effects, is -0.089, implying that a one-standard-deviation increase in the KII is associated with a $\sim 9\%$ decrease in GDP per capita within country. These estimate are strikingly similar to those in Table 1, which imply that a one-standard deviation increase in the KII is associated a $\sim 39\%$ decrease in luminosity per capita, and a $\sim 10\%$ decrease within country.

Columns 5 to 7 parallel the specifications in Table 1 with additional controls for the subsistence variables, political hierarchies, and the malaria index. In column 8, we control for cumulative oil and gas production and for the dummy indicating whether the national capital is located in the region. Appendix Table B.3.2 shows the results for the sample obtained with the direct-matching method. The results remain robust across all of these alternative specifications.

[15]These additional controls, from Gennaioli et al's (2014) region-level dataset, are only available at the region level and so could not be included in our other analyses.

Notes: Each observation is a region-year in the analysis sample obtained with the language-tree matching method. The geographic controls include temperature, precipitation, agricultural suitability, absolute latitude, elevation, ruggedness, distance to coast, and distance to nearest river or lake. The subsistence variables measure the weighted fraction of a region's ethnicities' subsistence economies that depend on hunting, fishing, animal husbandry, and agriculture (with gathering as the omitted category). Standard errors in parentheses are clustered at the country level. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

4.3 Spatial regression discontinuity analysis

Our estimates of the association between the KII and economic development are robust to the inclusion of a rich set of control variables, including geographic and cultural variables and country fixed effects. Despite this, it is possible that unobservable factors may confound our results. These unobservable factors could include, for example, geographic characteristics such as suitability for certain subsistence practices that co-determine kinship intensity and economic prosperity. They could also include contemporary unobservable factors associated with remoteness; for example, it is possible that limited government reach or lack of infrastructure may simultaneously increase kinship intensity and hamper economic activity.

To address these concerns, we conducted a spatial regression discontinuity (RD) analysis, following Michalopoulos and Papaioannou (2013) and Moscona et al. (2020). We compared the luminosity of pixels that are geographically close to one another but belong to the homelands of neighboring ethnicities that vary in their kinship intensity. This estimation strategy helps account for unobservable factors—including those tied to geography, history, or infrastructure—that vary smoothly across space.

For our baseline RD analysis, we restrict the sample to pixels that belong to pairs of contiguous ethnicities and that are within 200 km of the ethnic boundary that separates the two ethnicities. In addition, to address concerns that country-level unobservables such as national institutions may bias the estimates, we further restrict the sample to pairs of ethnicities located in the same country. We only use ethnicity pairs matched with the direct-matching method (see Section 3.3), both to ease the computational burden and to reduce imprecision stemming from the comparison of neighboring ethnicities with imputed KII values.

Figure 5 illustrates this setup for a pair of contiguous ethnicities in Zimbabwe: the Ndebele and the Venda. All pixels within 200 km of the boundary are included, with the

exception of pixels that fall directly onto an ethnic boundary or a country border (since those pixels cannot readily be attributed to only one ethnicity or country). The Venda, whose KII is 1.948, have higher kinship intensity than the Ndebele, whose KII is −0.159.

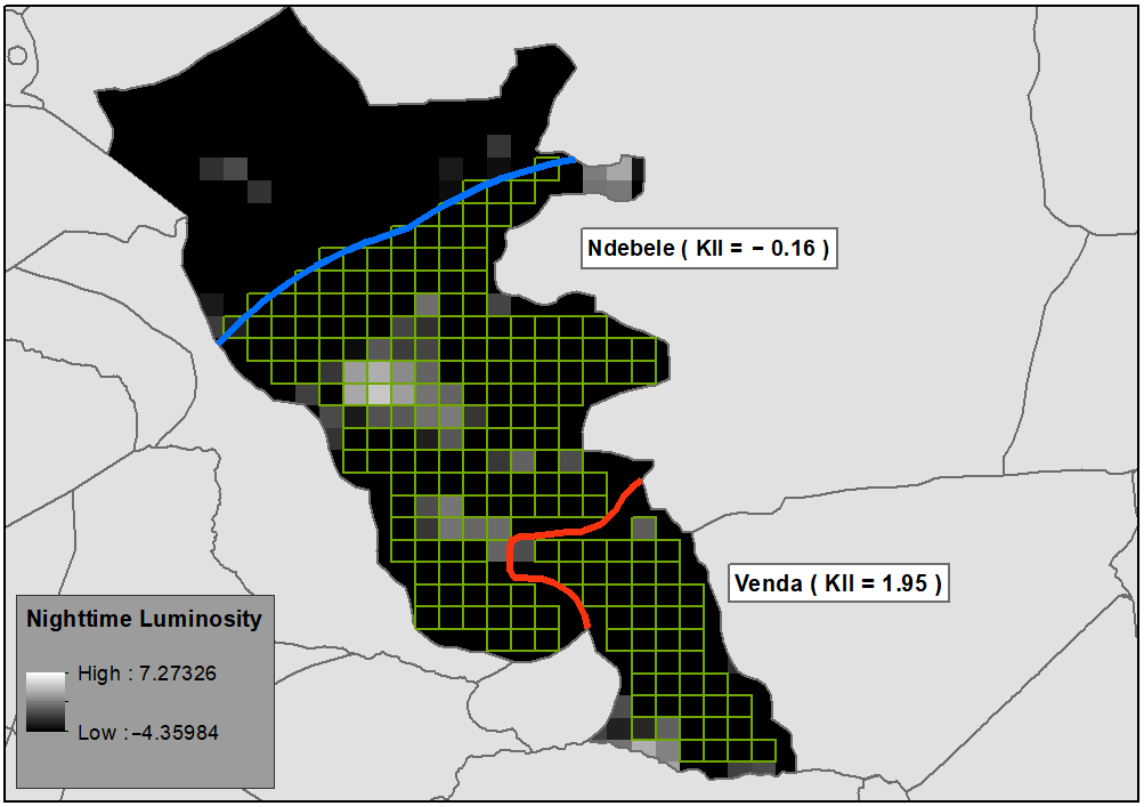

Figure 5: The map shows the nighttime luminosity of the pixels (marked by green squares) for a pair of contiguous ethnicities in Zimbabwe which are included in our analysis: the Ndebele (to the North) and the Venga (to the South). The red line is the ethnic boundary that separates the two ethnicities, and the blue line is located 200 km away from it. We drop pixels whose centroid is not located within 200 km of the ethnic boundary. The whole territory of Venda is within 200 km of the ethnic boundary, therefore, is included in the analysis. Our analysis only includes pixels that are not crossed by any other ethnic boundaries (the red line) or national borders (Gray borders). The Venda have a higher kinship intensity than the Ndebele.

We begin by graphically examining the relationship between luminosity and the distance to the boundary separating the ethnicities in the pairs, for the set of pixels used in our baseline analysis. Figure 6 shows a binned scatterplot of log luminosity residualized on log population density (on the y-axis) vs. distance to the ethnic boundary (on the x-axis). Distance to the boundary is negative for pixels in the homeland of an ethnicity that has the lower KII in a pair, and positive for the ethnicity with the higher KII. The figure clearly reveals the discontinuity at the boundary. While luminosity is rather uniformly distributed to the left and to the right of the boundary, it sharply drops at the ethnic boundary as we move from the relatively low to the relatively high KII ethnicities.

Next, to implement our formal spatial RD analysis, we adopt the following baseline specification:

$$L_{i,e(e'),c} = \beta KII_e + \delta \log(P_{i,e,c}) + \gamma X_{i,e,c} + \theta V_{(i),e} + \lambda_{ee',c} + f(D_{i,e(e'),c}) + \epsilon_{i,e(e'),c}. \quad (2)$$

The dependent variable $L_{i,e(e'),c}$ is the natural logarithm of the nighttime luminosity of pixel i in the homeland of ethnicity e that is adjacent to the homeland of ethnicity e', with

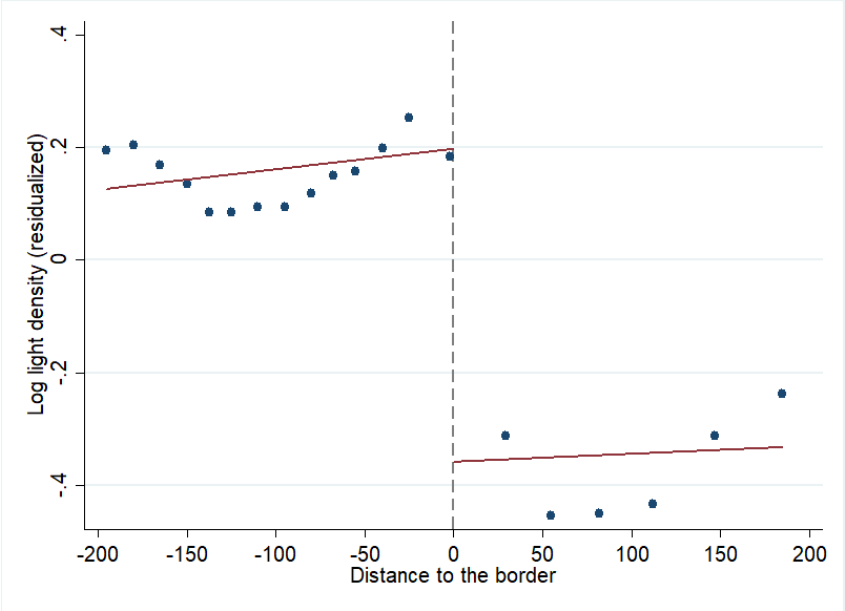

Figure 6: Binned scatterplot (with 20 bins) of the relationship between distance to the boundary and luminosity, across pixels located in the homelands of pairs of adjacent ethnicities in the same country. The y-axis shows log luminosity residualized on log population density. The x-axis shows the distance to the boundary in kilometers, with negative distances for pixels associated with the ethnicity with the lower KII in a pair, and positive distances for the ethnicity with the higher KII. The average KII across the pixels that belong to ethnicities with the relatively low KII is -1.54; for the ethnicities with the relatively high KII, it is 0.09. (There are fewer bins with positive distances, reflecting the fact that the homelands of ethnicities with lower KII tend to be larger and thus contain more pixels.)

both e and e' in the same country c.[16] We include ethnicity-pair fixed effects ($\lambda_{ee',c}$), which account for all (unobserved) factors unique to each ethnicity-pair. Following Moscona et al. (2020) and Gelman and Imbens (2019), we also include a local linear polynomial in the geodesic distance of each pixel's centroid from the boundary between the two adjacent ethnicities, $f(D_{i,e(e'),c})$, with different coefficients on the distance term for the relatively high and the relatively low KII ethnicities in the pairs. As in equation (1), KII_e is the KII for ethnicity e, $P_{i,e,c}$ is the pixel's population density, $X_{i,e,c}$ is the vector of geographic controls, and $V_{(i),e}$ denotes additional controls (in some regressions).

Table 3 reports the results for this baseline specification. In column 1, without the geographic controls, the estimated coefficient on the KII is $\hat{\beta} = -0.06$, which implies that a one-standard deviation increase in the KII is associated with a $\sim 6\%$ decrease in luminosity. Adding the baseline geographic controls in column 2 increases β only slightly in magnitude, to -0.072. Since all the ethnicity pairs in our RD analysis sample are in the same country, we can compare this estimate to those of the earlier OLS regressions with country fixed effects. With log luminosity and log regional GDP per capita as the dependent variables, the earlier corresponding estimates, reported in column 4 of Table 1 and of Table 2, were -0.096 and -0.090. This reveals a noteworthy consistency across the results of our three main empirical specifications so far.

In columns 3–5, $\hat{\beta}$ remains fairly stable when we add controls for the subsistence variables, political hierarchies, and the malaria index. Similarly, clustering at the language-family level or two-way clustering at both the country and language-family levels (columns

[16]Note that a pixel can enter the regression multiple times as separate observations if the ethnicity in whose homeland it falls is in pairs with multiple contiguous ethnicities.

6 & 7) does not appreciably impact the standard errors.

Table 3: The KII and nighttime luminosity: spatial RD analysis

Notes: Each observation is a pixel that belongs to an ethnicity in a pair of contiguous ethnicities in the same country, and within 200 km of the boundary between the two ethnicities. The geographic controls include temperature, precipitation, agricultural suitability, absolute latitude, elevation, ruggedness, distance to coast, and distance to nearest river or lake. "Distance-to-the-boundary polynomial" is the geodesic distance of each pixel's centroid from the boundary between the two adjacent ethnicities; we allow the coefficient on the distance term to differ between the relatively high and the relatively low KII ethnicities in the pairs. The subsistence variables measure the fraction of an ethnicity's subsistence economy that depends on hunting, fishing, animal husbandry, and agriculture (with gathering as the omitted category). Standard errors in parentheses are clustered at the country level (in columns 1–5), language family (in column 6), and two-way clustered at both the country and language-family levels (in column 7). *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

Table 4 shows the results of additional robustness checks. In columns 1 and 2, we exclude ethnicity-pairs for which the difference in KII is less than 0.1 or 1 standard deviations, respectively. In column 3, to address concerns that some pixels that are part of a large number of ethnicity-pairs receive too much weight in the regressions, we drop pixels that are part of more than 20 different ethnicity pairs. In column 4, we include pairs of neighboring ethnicities that are located in different countries and include country fixed effects in the regression. Finally, in columns 5 and 6, we use alternative approaches to control for the pixels' distances to the ethnic boundaries. Column 5 interacts the distance-to-the-boundary polynomial with ethnicity-pair fixed effects, and so includes a different coefficient on the distance term for each ethnicity in each of 785 ethnicity pairs. This is a demanding specification, but it allows us to control for distance patterns specific to each ethnicity in each pair. In column 6, rather than controlling for the distance to the boundary, we interact the longitude and latitude of each pixel with ethnicity-pair fixed effects; this specification controls more directly for features that vary in two-dimensional space in the homelands of each ethnicity pair. The results are robust to these alternative specifications.

For several reasons, our analysis so far may underestimate the true magnitude of β. First, our estimates may capture the spillover effects of light across ethnic boundaries—i.e., some pixels may appear brighter than they actually are due to overglow from bright nearby pixels in the neighboring ethnicity's homeland. Second, the fraction of the population belonging to each ethnicity may not change discontinuously at the ethnic boundary, for instance due to intermarriage, trade, or the presence of multi-ethnic urban agglomerations.

Notes: Each observation is a pixel that belongs to an ethnicity in a pair of contiguous ethnicities in the same country (except in column 4), and within 200 km of the boundary between the two ethnicities. The geographic controls include temperature, precipitation, agricultural suitability, absolute latitude, elevation, ruggedness, distance to coast, and distance to nearest river or lake. In columns 1–4, "Distance-to-the-boundary polynomial" is the geodesic distance of each pixel's centroid from the boundary between the two adjacent ethnicities; we allow the coefficient on the distance term to differ between the relatively high and the relatively low KII ethnicities in the pairs. In columns 1 and 2, we drop ethnicity pairs whose KII differences is less than 0.1 and 1 standard deviations, respectively. In column 3, we drop pixels that appear in more than 20 ethnicity pairs. In column 4, we also include in the analysis ethnicity pairs with ethnicities in different countries, and include country fixed effects in the regression. Column 5 interacts the distance-to-the-boundary polynomial with ethnicity pair fixed effects, and column 6 interacts instead each pixel's latitude and longitude with ethnicity-pair fixed effects. Standard errors in parentheses are clustered at the country level. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

To address these concerns, table 5 presents specifications using subsets of pixels that fall within different ranges of distances to the ethnic boundary. In columns 1 to 3, we still start at the boundary, but reduce the maximal distance to the boundary from 200 km (our baseline specification, also reported in column 2 of Table 3) to 150 km and then 100 km. In columns 4–6 and 7–9, to mitigate potential bias due to light spillovers and the smooth variation in population composition across boundaries, we drop pixels that are within 25 km and 50 km of the boundary, respectively.

The estimates are remarkably robust to using these alternative subsets of pixels. Consistent with our intuition that light spillovers and the smooth variation in population composition at the boundary may bias our estimates downward, the estimates become larger in magnitude as we drop pixels that are within 25 m and then 50 km of the ethnic boundary. When the pixels within 50 km of the boundary of dropped, our estimates imply that a one-standard-deviation increase in the KII is associated with a decrease of $\sim 11\%$ $(= (1 - e^{-0.12}) \cdot 100\%)$ in luminosity.

Our spatial RD analysis helps accounts for potential bias from unobservables that vary smoothly across ethnic boundaries. While it is not possible to test whether there are unobservables that vary discontinuously at the boundary, we can conduct a "placebo" RD analysis and examine whether observable variables show any signs of discontinuities at the boundaries. To do so, we estimated equation (2) again in our baseline analysis sample of pixels, but dropped the geographic controls and swapped the dependent variable, log luminosity, for each of our geographic controls in turn. The results, reported in Appendix Table B.4.2, show that the estimated coefficients on the KII are not significant at the 5%

Table 5: Spatial RD analysis with pixels at various distances from the ethnic boundaries

	Log nighttime luminosity

Number of clusters	70	70	70	70	70	70	70	70	70

Notes: Each observation is a pixel that belongs to an ethnicity in a pair of contiguous ethnicities in the same country. The various specifications are identical, but the analysis samples include pixels located at different ranges of distances from the boundary separating the two ethnicities in a pair. The geographic controls include temperature, precipitation, agricultural suitability, absolute latitude, elevation, ruggedness, distance to coast, and distance to nearest river or lake. "Distance-to-the-boundary polynomial" is the geodesic distance of each pixel's centroid from the boundary between the two adjacent ethnicities; we allow the coefficient on the distance term to differ between the relatively high and the relatively low KII ethnicities in the pairs. Standard errors in parentheses are clustered at the country level. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

level for any of the geographic controls.[17] Overall, we find no evidence that discontinuities in observable geographic characteristics are present at ethnic boundaries.

5 The inbreeding coefficient, kinship intensity, and economic development

To address potential shortcomings of using the KII as a measure of kinship intensity, we used genetic data to compute the inbreeding coefficient for individuals in the Human Origins (HO) dataset (Reich Lab, 2020). The inbreeding coefficient, denoted F, is a core variable in population genetics that measures the relatedness of ones' parents. HO contains genetic data on 9,460 present-day individuals and 3,723 ancient individuals [18] from populations around the world, compiled from previously published genetics studies (including Jeong et al., 2019; Lazaridis et al., 2014, 2016; Lipson et al., 2018; Nakatsuka et al., 2017; and Pickrell et al., 2012). We matched the present-day HO individuals to Ethnologue ethnicities and used the ethnicities' average inbreeding coefficients as our alternative measure of kinship intensity.

We begin this section by briefly describing the inbreeding coefficient as well as the methodology we used to estimate it, and by defining several additional variables we computed with the HO genetics data. Appendix C provides further detail. Next, we examine the inbreeding coefficient's associations with kinship intensity, and then with economic development.

[17] The estimated coefficient is significant at the 10% level when "distance to coast" is the dependent variable, but this may be a false positive due to multiple hypothesis testing.

[18] The ancient individuals lived between $\sim 88,000$ BCE and ~ 1900 CE; we did not analyze their data.

5.1 The inbreeding coefficient and other genetic variables

Inbreeding occurs when two related individuals mate and produce offspring. Related individuals share DNA from one or more common ancestors, and thus inbreeding increases the probability that at a given location on a chromosome, their offspring inherits identical DNA segments on the maternal and paternal copies of the chromosome (Ceballos et al., 2018). (Recall that humans have 23 pairs of chromosomes: they inherit one of the chromosomes in each pair from their mother and the other from their father.) First cousins, for instance, share both a grandmother and a grandfather, so some DNA segments they inherited from their shared grandparents will be identical across their two genomes. As a result, if two first cousins mate and produce a child, that child will have locations in their genome where they will have inherited identical DNA segments from their two cousin parents, coming originally from the same grandmother or grandfather. The maternal and paternal variants at such genomic location are said to be homozygous—since they are identical—and identical-by-descent (IBD)—since they can also be traced back to one common ancestor.

A common measure of the intensity of inbreeding is called the coefficient of inbreeding, denoted F. F measures the probability that the maternal and paternal variants at a location in the genome are IBD, and is also equal to the expected fraction of the genome that is IBD for a given individual. An individual's F coefficient is typically equal to the coefficient of kinship, or one-half the coefficient of relationship, between their two parents (Cavalli-Sforza and Bodmer, 1999; Falconer and Mackay, 1996). The latter is a measure of the relatedness between the two parents; for example, the expected F coefficient of the offspring of two second-degree cousins is 0.015625 ($= \frac{1}{2} \cdot \frac{1}{62}$), whereas it is 0.0625 ($= \frac{1}{2} \cdot \frac{1}{8}$) for the offspring of first-degree cousins and 0.25 ($= \frac{1}{2} \cdot \frac{1}{2}$) for the offspring of two siblings. Thus, F measures the degree to which an individuals' two parents are related, and a population's average F should in principle correlate positively with its KII, and with its rate of cousin marriage in particular.

Various methods have been developed to estimate F using an individual's genetic data. Our main measure of F, denoted F_{ROH}, is the fraction of an individual's autosomal genome that contains runs of homozygosity (ROHs) of at least 1.5 Mb in length. The autosomal genome comprises the 22 pairs of chromosomes other than the sex (X and Y) chromosomes, and ROHs are continuous segments of homozygous variants. Because the length of the autosomal genome is estimated at 3,000 Mb[19] (Clark et al., 2019), an individual's F_{ROH} can be calculated as

$$F_{ROH} = \sum_i \frac{l_i}{3,000}, \tag{3}$$

where the sum is over the individual's ROHs that are at least 1.5 Mb in length and l_i is the length of ROH i in Mb.

Longer ROHs (e.g., ROHs at least 1.5 Mb in length) typically result from inbreeding (Ceballos et al., 2018) and have been shown to correlate positively with pedigree-based estimates of inbreeding (Kang et al., 2017; McQuillan et al., 2008; Pemberton and Rosenberg, 2014) and with population-level cousin marriage preferences (Sahoo et al., 2021). Below in Section 5.2, we too find that F_{ROH} (or, equivalently, longer ROHs) correlates positively with cousin marriage preferences; we also find that F_{ROH} correlates positively with the KII.

[19] A megabase (Mb) is a unit of physical distance in the genome

We estimated F_{ROH} for 4,756 present-day individuals in the Human Origins (HO) data set whose genetic data were collected using the Affymetrix Human Origin genotyping array and who passed a number of quality control filters. As we describe in more detail in Appendix C, we used the ROHgen2 software pipeline developed by the ROHgen consortium (Clark et al., 2019)[20] to estimate F_{ROH}, and conducted diagnostic checks to verify the reliability of our F_{ROH} estimates. We then matched the HO individuals to 551 Ethologue ethnicities using a procedure that resembles the direct matching method described in Section 3.3 that we used to match the EA data. We computed the average F_{ROH}, which we denote $\overline{F_{ROH}}$, across the HO individuals matched to each ethnicity. We dropped ethnicities with fewer than eight individuals, leaving 416 ethnicities in the sample. For our main analysis with $\overline{F_{ROH}}$—of its relationship with luminosity at the pixel level—we further dropped pixels that did not pass the filters described in Sections 3.1 and 3.3, thus leaving 281,177 pixels that fall in the homelands of 245 ethnicities.

We note that while F is the fraction of the genome that is IBD, F_{ROH} is the fraction that is in ROHs longer than 1.5 Mb. Because some ROHs that are shorter than 1.5 Mb are IBD and some longer ROHs are not IBD, F_{ROH} is not a perfect measure of F. ROHs can arise in individuals for a variety of reasons unrelated to marital practices and kinship systems. Using only ROHs that are at least 1.5 Mb long to compute F_{ROH} helps mitigate, but does not eliminate, concerns that F_{ROH} may capture influences other than consanguineous marriage practices and intensive kinship.

For these reasons, we also used the HO genetic data to compute the following "genetic controls" that may correlate with F_{ROH} but are unrelated to kinship intensity and consanguineous marriage practices, and included them in our empirical analyses as controls:

- *Expected heterozygosity*: Expected heterozygosity is a measure of genetic diversity in a population and is defined as the probability that two randomly selected individuals from a population have different genetic variants at a randomly selected location on one chromosome in the genome. Expected heterozygosity has been shown to correlate negatively across populations with mean F estimated with genetics data (Pemberton and Rosenberg, 2014) and to correlate nonlinearly across countries with economic development (Ashraf and Galor, 2013). Expected heterozygosity decreases with *migratory distance from East Africa*, consistent with a migration model that predicts increased genetic drift and decreased heterozygosity with increased distance from Africa (Ramachandran et al., 2005). We also include migratory distance from East Africa among our "genetic controls".

- *The top 20 principal components of the genotypic data*: We computed the top 20 principal components (PCs) of the genotypic data for each individual and took the average value of each PC in each ethnicity. It has been shown that the top PCs are good proxies for individuals' geographic origins and that including them as controls in regressions helps mitigate bias related to population stratification (Novembre et al., 2008; Price et al., 2006). (Population stratification refers to systematic differences in genetic variants' frequencies that correlate with cultural or environmental differences (Hamer, 2000).)

- *Mean regional pairwise* F_{ST}: Both F and F_{ROH} tend to be inflated in populations that are genetically isolated (due to geographical or cultural distance or taboos

[20]The ROHgen consortium is a large consortium of research groups that seeks to estimate the effect of inbreeding on various traits (Clark et al., 2019; Joshi et al., 2015).

prohibiting mating with individuals from other populations—see Pemberton and Rosenberg (2014)). In such populations, reduced mate choice can lead to increased cryptic inbreeding, in which two parents may have a recent common ancestor by chance and not due to a deliberate cultural practice of mating relatives. Following Pemberton and Rosenberg (2014), we estimate the degree of genetic isolation of a population using the average pairwise genetic distance "F_{ST}" between that population and other populations in the same geographic world region with sufficient sample sizes.

Appendix C provides additional details on these genetic controls and Appendix Table B.5.1 shows summary statistics for $\overline{F_{ROH}}$ and these genetic controls (except the PCs, whose scale is arbitrary). Across 416 Ethnologue ethnicities, $\overline{F_{ROH}}$ ranges from 0.003 to 0.146, with a mean of 0.020 and a standard deviation of 0.018. To put these figures in perspectives, two populations in which everyone were the offspring of second-cousin and uncle-niece unions would have mean F of 0.015625 and 0.125, respectively, close to the mean and maximum $\overline{F_{ROH}}$ in our sample. We estimated the mean $\overline{F_{ROH}}$'s of the English, Kurux, and Eastern Balochi (the three ethnicities for which we provided brief ethnographies in Section 2.2) to be 0.0065, 0.0157, and 0.0617, respectively.

5.2 The inbreeding coefficient and kinship intensity

As mentioned above, F_{ROH} has been shown to correlate with inbreeding and consanguineous marriage preferences and practices (Ceballos et al., 2018; Kang et al., 2017; McQuillan et al., 2008; Pemberton and Rosenberg, 2014; Sahoo et al., 2021). In theory, polygyny and endogamy should also increase inbreeding. To further validate our estimates of $\overline{F_{ROH}}$ as a proxy for kinship intensity, we examined its association with our *cousin marriage preference* KII sub-indicator as well as with the KII itself.

Across the 398 ethnicities with non-missing data, the correlation between $\overline{F_{ROH}}$ and the cousin-marriage-preference sub-indicator is 0.28; after partialling out the effects of the genetic controls from $\overline{F_{ROH}}$, the correlation increases to 0.32. Unsurprisingly, given that the cousin-marriage-preference sub-indicator is one of the five components of the KII and that some other dimensions of the KII can impact consanguinity, $\overline{F_{ROH}}$ also correlates with the KII ($\hat{r} = 0.26$), though the correlation is lower if $\overline{F_{ROH}}$ is first residualized on the genetic controls ($\hat{r} = 0.14$).

Table 6 shows the results of regressions of the cousin-marriage-preference sub-indicator and of the KII on $\overline{F_{ROH}}$. In all specifications, the coefficient on $\overline{F_{ROH}}$ is highly statistically significant and large in magnitude. For instance, in the regressions in columns 2 and 6 with the genetic controls, the coefficient estimates of 45.744 and 13.185 imply that the cousin-marriage preferences and KII of an ethnicity in which everyone is the offspring of second cousins ($\overline{F_{ROH}} = \frac{1}{64} = 0.015625$, assuming no influences other than inbreeding), are ~ 0.7 and ~ 0.2 standard deviations higher than those of an ethnicity in which everyone is the offspring of unrelated parents ($\overline{F_{ROH}} = 0$). Further, $\overline{F_{ROH}}$ accounts for a nontrivial share of the variation in cousin marriage preferences: its incremental R^2, defined as the difference in R^2 between the regression on $\overline{F_{ROH}}$ and the controls and the same regression but on the controls only, is 0.095. As shown in Appendix Table B.5.2, these results are robust to alternative specifications.

PRELIMINARY DRAFT: DO NOT CIRCULATE OR CITE

Table 6: The inbreeding coefficient and kinship intensity

Notes: Each observation is an ethnicity from the Ethnologue. The genetic controls include expected heterozygosity, migratory distance from East Africa, the top 20 PCs, and mean regional pairwise F_{ST}. $\Delta R^2(\overline{F_{ROH}})$ is the incremental R^2 of $\overline{F_{ROH}}$, defined as the difference in R^2 between the regression on $\overline{F_{ROH}}$ and the controls and the regression on the controls only. Standard errors, clustered at the country-level, are in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

5.3 The inbreeding coefficient and nighttime luminosity

Table 7 reports the results of regressions of luminosity on $\overline{F_{ROH}}$ across pixels. The analysis mirrors that of the association between luminosity and the KII in Section 4.1, but with $\overline{F_{ROH}}$ substituted for the KII as the explanatory variable of interest and with the genetic controls also included in the regressions (except in column 1).

Consistent with our estimates of a negative relationship between luminosity and the KII, the association between luminosity and $\overline{F_{ROH}}$ is consistently negative and is significant at the 5% level in all specifications. When population density and the genetic and geographic controls are included (in column 3), the coefficient estimate of -25.841 implies that log luminosity is 0.40 $(= 25.841\frac{1}{64})$ units lower, and luminosity $\sim$ 33% $(= (1 - e^{(-25.841\frac{1}{64})}) \cdot 100\%)$ lower, for an ethnicity in which everyone is the offspring of second cousins than for an ethnicity in which everyone is the offspring of unrelated parents. These results are robust to controlling for continent and country fixed effects (columns 4 and 5); for the subsistence variables, political hierarchies, and the malaria index (columns 6–8); as well as to clustering standard errors at the language-family level and two-way at both the country and language-family levels (columns 9–10).

Appendix Table B.6.2 reports additional regressions we conducted to further assess the robustness of the results. The results remain significant when the genetic controls are dropped from the regression. As mentioned above, for our baseline analyses, we dropped ethnicities to which fewer than 8 HO individuals could be matched. Columns 2–4 explore the sensitivity of the results to using alternative cutoffs of 5, 10, and 15 individuals. The association between luminosity and $\overline{F_{ROH}}$ is robust to using a cutoff of 5 individuals; with cutoffs of 10 and 15 individuals, the estimated coefficient on $\overline{F_{ROH}}$ slightly shrinks in magnitude (but remains negative) while the standard error increases, and the association loses significance. Given that relatively few individuals were sampled for each ethnicity we analyzed (see Appendix Table B.5.1) and that they were sampled by different teams of researchers with different protocols, this lack of robustness is not particularly surprising.

These results raise the question of what mechanisms are responsible for the association between between kinship intensity and the inbreeding coefficient on the one hand and luminosity on the other. One potential mechanism is inbreeding depression (ID), whereby

Notes: Each observation is a pixel. The genetic controls include expected heterozygosity, migratory distance from East Africa, the top 20 PCs, and mean regional pairwise F_{ST}. The geographic controls include temperature, precipitation, agricultural suitability, absolute latitude, elevation, ruggedness, distance to coast, and distance to nearest river or lake. The subsistence variables measure the fraction of an ethnicity's subsistence economy that depends on hunting, fishing, animal husbandry, and agriculture (with gathering as the omitted category). Standard errors in parentheses are clustered at the country level in all regressions, except in column 9, where they are clustered at the language-family level, and in column 10, where they are clustered two-way at both the country and language-family levels. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

the offspring of related individuals tend to have reduced biological fitness (including reduced health and cognitive performance). The following section explores potential mechanisms and shows that ID is unlikely to be the main driver of the association.

6 Mechanisms

Having established a strong and robust negative empirical association between kinship intensity and economic development, we now turn to the potential mechanisms. We describe and provide empirical evidence on the link between kinship intensity and key prosperity-promoting factors such as trade and the divisions of labor, impersonal prosociality, innovation, and institutions that protect property rights. Then, in Section 6.2, we discuss inbreeding depression (ID) as a further mechanism—but conclude that this mechanism is unlikely to be important.

6.1 Mechanisms linking kinship intensity to economic development

At the heart of economics are the concepts of comparative advantage, the division of labor, and trade. Division of labor leads to productivity gains and economic prosperity. Yet, division of labor and trade is closely tied to trust. As Arrow (1972) noted, "virtually every commercial transaction has within itself an element of trust... it can be plausibly argued that much of the economic backwardness in the world can be explained by the lack of mutual confidence". Existing studies provide robust evidence that kinship intensity

and the strength of family ties is a major predictor of low levels of out-group trust and impersonal cooperation (Enke, 2019). Consequently, low levels of out-group trust in kinship intense societies will hamper the division of labor, trade, and ultimately economic prosperity. Here, we provide consistent evidence that in addition to out-group trust high kinship intensity is negatively associated with the division of labor and trade both among ethnicities (table 8) and countries (table 9).

Out-group trust is only one aspect of psychology. In Schulz et al. (2019) we document that weak kin-based institutions are associated with a whole psychological bundle including higher levels of individualism and independence, impersonal cooperation, and lower levels of conformity and obedience, while Schulz (2022) documents that political participation is lower among societies with strong kin-based institutions. This suggest that kinship intensity affects economic prosperity through several additional channels.

First, Gorodnichenko and Roland (2016) have shown that individualism is associated with innovation and higher GDP. They argue that individualist culture creates incentive for innovation by awarding social status to personal accomplishments such as important discoveries. Furthermore, innovations will diffuse faster in societies with diverse kin networks, while it is easier to enforce long-standing traditions inimical towards innovations in the strong cohesive kin groups of societies with high kinship intensity. Low kinship intensity should therefore be associated with less innovations; a relation that we document among countries in table 9.

Second, a large literature stresses the importance of well-functioning political and economic institutions that secure property rights for economic prosperity (Coase, 1960; North et al., 2009; Acemoglu and Robinson, 2012). Yet, strong loyalty demands towards kin can undermine well-functioning formal large-scale inclusive institutions (Greif, 2006a; Greif and Tabellini, 2017; Greif, 2006b; Henrich, 2020). Schulz (2022) has shown that across the world, among countries, regions and ancestral ethnicities, high kinship intensity is associated with more autocratic rule and less participation in the political process, while Akbari et al. (2019) and Akbari et al. (2020) show how cousin marriage is associated with more corruption. The quality of institutions is therefore likely one mechanism linking high kinship intensity to low economic prosperity.

Lastly, – and highly related to impersonal trust as well as the quality of institutions – kinship intensity is related to impersonal cooperation. Peoples' willingness to cooperate (e.g., via tax compliance) is key for the provision of public goods and other cooperative endeavors such as public education, infrastructure, law enforcement, and the court system. Ultimately, these cooperative endeavors are not only important for individual well-being but also for entrepreneurial activity and economic prosperity.

These theoretical consideration based on existing empirical findings suggest that several mechanisms link kinship to economic prosperity. Those mechanisms are highly related to each other and we do not aim to disentangle the relative importance of each mechanisms. Rather, here, we provide correlative empirical evidence in support of each of those different mechanisms.

First, we provide evidence on the negative relation between high kinship intensity and the division of labor among ancestral ethnicities. Table 8 reports the ethnicity analysis in which we use three different dependent variables. The first is a Specialization index constructed based the Ethnographic Atlas (EA). The EA contains data on labor specialization in 11 different tasks.[21] Specialization in each task can take on one of

[21]The tasks are metal working, weaving, leather working, pottery, boat building, house building, gathering, hunting, fishing, animal husbandry, and agriculture.

three values: 0: no or only age specialization, 1: craft specialization, or 2: industrial specialization. The Specialization index is constructed by summing over the values of all 11 tasks and standardizing the resulting sum.[22]

Conceptually related to labor specialization, is market exchange. Based on the Standard Cross-Cultural Sample we created two measures. The first measure captures the degree of intercommunity trade as food source (4-point scale: 0: no trade or food imports absent, 1: less than 10 percent, 2: less than 50 percent, 3: more than 50 percent), while the second measure captures the production for market exchange. The latter is a binary measures that takes a value of 0 if production for consumption is more important than production for market exchange.

Regression table 8 reveals a robust association between the KII and the specialization index. A one-standard deviation increase in the KII is associated with roughly a 0.144 standard deviation decrease in specialization. This relation holds controlling for the standard geographic controls, subsistence (columns 2 & 3), and country fixed effects (column 3).[23] We conservatively clustered the standard errors at the language family. This addresses concerns about the non-independence of the errors terms due to shared cultural histories. Clustering at the country level decreases the standard errors such that all coefficients for the Specialization index are significant at least at the 1-percent level.

In the smaller sample of the SCCS, we do not find a significant relation between the KII and Intercommunity food trade (column 4), while there is a significantly negative relation between Market participation and the KII (column 5). The insignificant result in column 4 may reflect that Intercommunity trade focuses narrowly on food which may be a noisy measure for the overall degree of market exchange since food may be more frequently produced for self-consumption or within community trade compared to other products.

Table 9 reports on the cross-country regressions. Our theoretical consideration that kinship intensity will affect a whole bundle of factors conducive for economic growth is reflected in the reported outcome variables. While we control for the standard set of geographic covariates, it is clear that the aim of this analysis is to present correlative evidence in support of our theoretical consideration while acknowledging that we are not addressing all potentially confounding factors. Column 1 reports on a country's openness to trade (the sum of imports and exports as a share of GDP). Consistent with our hypothesis we find (weakly significant) evidence that in high-KII countries cross-country trade is relatively lower. Columns 2 and 3 report on the relationship between the KII and innovation. High-KII is associated with a lower number of scientific and technical articles (column 2) and a lower—though insignificant—number of patents (column 3). Columns 4 to 6 report on the relationship between the KII and institutional quality. We focus on cross-country indicators of institutions that are important for doing business, namely, expropriation risk (column 4), institutional quality[24] (column 5) and corrup-

[22] In our regression analysis, we included all ethnicities that had data entries for at least 8 tasks. Missing data for a specific task was coded as 0 and we included 11 dummy variables capturing whether data for a task was missing. We followed a similar procedure in case a task was coded absent for a particular ethnicity. In this case the tasks was coded as 0, while a separate set of dummy variables capture whether a task in a particular ethnicity was coded as absent.

[23] We report country fixed effects regression mainly for parsimony with our main analysis. However, since both the KII and the dependent variables capture ancestral characteristics at a time that many contemporary county boarders did not exist in its current form, the country fixed effects can be interpreted more broadly as capturing the *local* relation between the KII and proxies for market exchange

[24] This variable is constructed based on the Enterprise survey and Doing-business reports and captures

Table 8: Ethnicity-level KII, specialization, and market exchange

VARIABLES	(1) Specialization	(2) Specialization	(3) Specialization	(4) Intercommunity food trade	(5) Market participation

R-squared	0.557	0.576	0.738	0.257	0.272
Number of clusters	125	125	125	74	49

Notes: Ethnicity-level regression of the Specialization index (columns 1–3), Intercommunity food trade (column 4) and Market production (column 5) on the KII. All columns control for the standard geographic covariates (precipitation, temperature, agricultural suitability, absolute latitude, ruggedness, elevation, and distance to the coast) and columns 2 to 5 include variables capturing subsistence (reliance on hunting, gathering, fishing, animal husbandry, and agriculture). In columns 1 to 3 we include a set of dummy variables capturing for each of the 11 tasks whether it is absent in an ethnicity and a set of dummy variables capturing whether the entry is missing in the Ethnographic Atlas (included in columns 1 to 3 are all ethnicities with at least 8 non-missing entries). Standard errors clustered at the language family are reported in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

tion perceptions (column 6). Consistent with our hypothesis and previous findings, a higher KII is significantly associated with a higher expropriation risk (column 4), lower institutional quality (column 5) and higher perceived corruption (column 6). Lastly, we replicate that finding in Schulz et al. (2019) and show that the KII is related to impersonal pro-sociality as proxied by voluntary blood donation to non-family members (column 7) and out-group trust (column 8). These two indicators are part of a larger psychological bundle; to complete the picture, we report the regression results of those other indicators in appendix.

Overall, thus, the empirical evidence supports the theoretical considerations that kinship intensity is related and possibly impacts key factors that that foster economic prosperity.

Table 9: Cross-country evidence on mechanisms

Notes: Country-level regression of variables capturing mechanisms (linking KII to economic prosperity) on the KII. In each regression, we include the set of standard geographic control variables (precipitation, temperature, agricultural suitability, absolute latitude, ruggedness, elevation, and distance to the coast). Robust standard errors are reported in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

institutional features conducive for conducting business.

6.2 Inbreeding depression (ID) and economic development

Inbreeding depression (ID) is the reduction in biological fitness and related traits (such as health, cognitive ability, and height) observed in the offspring of related individuals. Higher levels of ID are to be expected in intensive-kinship societies, since these societies tend to have more marriages between cousins or other relatives and more polygyny and endogamy. Indeed, our second main measure of kinship intensity is the inbreeding coefficient, which is a direct measure of inbreeding levels.

To assess the potential impact of ID on economic development, we compared our estimate of the association between the inbreeding coefficient and economic development across ethnicities to estimates from previous research of the effect of ID on educational attainment (EA). To our knowledge, the largest study to date of the effects of ID is Clark et al. (2019), whose software pipeline we used to compute F_{ROH}. Clark et al. (2019) estimated the effects of ID by regressing various individual-level outcomes on F_{ROH}. Their main estimates imply that the educational attainment (EA) of the offspring of second cousins is ~ 0.11 year lower (and their cognitive performance ~ 0.7 IQ points lower) than that of the offspring of unrelated individuals. This implies that the direct effect of ID would reduce the average EA of an ethnicity in which everyone were the offspring of second cousins by ~ 0.11 year.

We do not have comparable EA data at the level of the Ethnologue ethnicities, but to benchmark that figure, we used data from Gennaioli et al. (2014); across 1,190 subnational regions with nonmissing data for the year 2000, the mean average EA is 8.19 years and the standard deviation is 2.69 years. Thus, the direct effects of ID in the offspring of second cousins represents only $\sim \frac{1}{25}$ of the standard deviation in average EA across subnational regions.

By contrast, our estimate of -25.841 in column 3 of Table 7 implies that log luminosity for an ethnicity in which everyone is the offspring of second cousins is 0.40 units lower, conditional on log population density (and the other control variables). This represents nearly one fourth of the standard deviation of log luminosity residualized on log population density (1.76) across the 245 Ethnologue ethnicities in the analysis sample for that regression, and nearly half of the standard deviation of log luminosity residualized on log population density (0.89) across 1,209 subnational regions with nonmissing data for the year 2000 in the Gennaioli et al. (2014) data.

This exercise is necessarily imperfect due to the lack of data allowing for a direct comparison of the effect of ID to our estimates, but it illustrates that ID is unlikely to have sufficiently large effects to account for much of the association we document between kinship intensity and economic development.

7 Conclusion

We documented a strong statistical relationship between kinship intensity and economic prosperity. Higher kinship intensity is associated with lower economic prosperity. This holds at the pixel-level using a measure of kinship intensity based on anthropological records and nighttime luminosity as a proxy for economic development. It also holds across regions using regional GDP per capita as the outcome variable. Furthermore, it also holds among ethnicities based on genetic correlates of kinship intensity, i.e., a population's inbreeding coefficient. This measure is particularly interesting since it does not rest on self-reports, administrative records, or broad categories which makes it thus

a more objective measure.

And while the relationship holds across those different measures, it is hard to account for unobserved factors related to culture, geography, or contemporary institutions may bias our estimates. Yet, we show that the results are robust to the inclusion of a large set of covariates. The inclusion of country fixed effects addresses a major concern, namely, that country-level characteristics such as national political institutions, schooling, or social security systems bias our estimates. Moreover, we conduct a regression discontinuity design and show that the relationship holds. This addresses concerns that unobserved factors related to geographic including soil quality, but also remoteness and the associated limited reach of government confound our estimates. Taken together, thus, this paper provides evidence that high kinship intensity is detrimental to economic development.

We caution, however, against concluding that intensive kin-based institutions are less desirable and that policy should seek to dismantle them: in many places, intensive kin-based institutions play a critical role in providing a safety net and maintaining social order. Tight family network may also foster happiness and life satisfaction (Alesina Giuliano 2012).

PRELIMINARY DRAFT: DO NOT CIRCULATE OR CITE

A Data Appendix

A.1 Variables construction

Pixel-level variables: **Variable name**	**Description**
Nighttime luminosity	Nightlight luminosity (light emitted from a pixel divided by pixel area, also commonly referred to as light density) measured by satellites in the year 2010-2011. The Global Radiance Calibrated Nighttime Lights data is gridded with an output resolution of 30 arc-seconds. We aggregate the data to 0.125 × 0.125 degree pixels by taking the mean of 225 constituent pixels from raw data, and then divide it by fraction of component pixels covered by land. Source: Elvidge et al. (1999).
Population density	Population density (number of persons per square kilometer) in year 2010. The Gridded Population of the World (GPWv4) collected population input data at the most detailed spatial resolution available from the results of the 2010 round of Population and Housing Censuses, which occurred between 2005 and 2014. The input data are extrapolated to produce population estimates for different years. The data is adjusted to Match 2015 Revision of UN WPP Country Totals. GPWv4 is gridded with an output resolution of 30 arc-seconds. We aggregate the data to 0.125 × 0.125 degree pixels by taking the mean of 225 constituent pixels from raw data. Source: Center for International Earth Science Information Network - CIESIN - Columbia University, 2017. Gridded Population of the World, Version 4 (GPWv4).
Land and water area	Surface areas of land and water in square kilometers per pixel. The Land Area raster provides estimates of the land area, excluding permanent ice and water, within each pixel, and was used to calculate the population density rasters. The Water Area raster provides estimates of the water area (permanent ice and water) within each pixel. The sum of land area and water area of a pixel equals the total surface area of that pixel. The data files were produced as global rasters at 30 arc-second resolution. Therefore, we aggregate the data to 0.125 × 0.125 degree pixels by taking the sum of 225 constituent pixels from raw data. Source: Center for International Earth Science Information Network - CIESIN - Columbia University, 2017. Gridded Population of the World, Version 4 (GPWv4).
Temperature/Precipitation	Mean monthly temperature/precipitation over the period 1901-2017. The gridded Climatic Research Unit (CRU) Time-series (TS) data version 4.02 data are month-by-month variations in climate over the period January 1901 - December 2017, based on monthly observational data calculated from daily or sub-daily data by National Meteorological Services and other external agents, provided on 0.5 × 0.5 degree cells. Therefore, the 16 constituent 0.125 × 0.125 degree pixels of each cell are assigned with the same value. Source: University of East Anglia Climatic Research Unit; University of East Anglia Climatic Research Unit et al. (2017): CRU TS4.02.

Elevation	Mean elevation in 100 meters. The data is provided in a 30 arc-second resultion map by the Global 30 Arc-Second Elevation data set. We aggregate the data to 0.125×0.125 degree pixels by taking the mean of 225 constituent pixels from raw data. Source: U.S. Geological Survey, Global Digital Elevation Model (GTOPO30).
Ruggedness	Mean terrain ruggedness. As a measure of the local variance in elevation, terrain ruggedness at a point (an individual cell) is defined as the square root of the sum of the squared differences in elevation between the central point and the eight adjacent points. Formally, it is defined as follows. Let $e_{r,c}$ denote elevation at the point located in row r and column c of a grid of elevation points. Then the Terrain Ruggedness Index for this point is calculated as $\sqrt{\Sigma_{j=c-1}^{i=c+1}\Sigma_{i=r-1}^{i=r+1}(e_{i,j} - e_{r,c})^2}$. The data is calculated at the level of 30 arc-second cells on a regular geographic grid covering the Earth. The data is provided with the resolution of 30 arc-seconds. We aggregate the data to 0.125 degree pixels by taking the mean of 225 constituent pixels from raw data. Source: Nunn and Puga (2012).
Suitability for agriculture	The fraction of each grid cell that is suitable to be used for agriculture. It is based on the temperature and soil conditions of each grid cell. The data is constructed based on the global map (0.5×0.5 degree cells) obtained from Suitability for Agriculture. Therefore, the 16 constituent 0.125 degree pixels of each cell are assigned with the same value. Source: Ramankutty et al. (2002), Atlas of the Biosphere.
Distance to the nearest coast	Distances in kilometers from 0.125 degree pixel centroids to the nearest coast. Source: Natural Earth, Coastline.
Distance to the nearest river or lake	Distances in kilometers from 0.125 degree pixel centroids to the nearest river or lake centerline. Source: Natural Earth, River and Lake Centerline.
Malaria index	An index representing the contribution of regionally dominant biological characteristics of vector mosquitoes to the force of malaria transmission. The data is constructed based on the world map of 0.5×0.5 degree cells. Source: (Kiszewski et al., 2004).

PRELIMINARY DRAFT: DO NOT CIRCULATE OR CITE

Ethnicity-level variables: **Variable name**	**Description**
Cousin marriage preference	The variable is created based on entry EA026, then linked to contemporary populations and standardized. The variable takes value 0 if cousin marriage is not preferred, value 1 if second- (but not first-) cousin marriage is preferred, value 2 if cross-cousin marriage is preferred, value 3 if parallel-cousin marriage is preferred. To enlarge the sample, we predicted cousin marriage preference based on cousin terms in entry EA027 that contains data on cousin terms classified into eight categories (Crow, Descriptive, Eskimo, Hawaiian, Iroquois, Omaha, Sudanese, and Mixed). To predict cousin marriage preference, we first analyzed the sample of ethnicities with data on both cousin marriage preference and cousin terms. For each cousin term category, we calculated the mean of the cousin marriage sub-indicator. We used the resulting mean values to predict the expected cousin marriage preference sub-indicator for ethnicities where only data on cousin terms is available. Source: Ethnographic Atlas (Murdock, 1967; Kirby et al., 2016).
Polygamy	The variable is created based on entry EA009, then linked to contemporary populations and standardized. The variable takes value 0 for monogamy, value 1 for occasional or limited polygyny, and value 2 for common polygyny and polyandary. Source: Ethnographic Atlas (Murdock, 1967; Kirby et al., 2016).
Co-residence of extended families	The variable is created based on entries EA008 and EA012, then linked to contemporary populations and standardized. We created a variable for domestic organization based on EA008 that takes value 0 for nuclear and polygamous families, 1 for minimal extended or stem families, 2 for small extended families and 3 for large extended families. We also created a second variable, marital residence based on EA012 that takes the value 0 for neolocality (spouses move to a new location), 1 for ambilocality (individuals can choose which side of the family they relocate to), and 2 for the remaining cases (e.g., patrilocality or matrilocality). We take the average of the domestic organization and marital residence variables to create the sub-indicator for the co-residency of extended families. Source: Ethnographic Atlas (Murdock, 1967; Kirby et al., 2016).
Lineage organization	The variable is created based on entry EA043, then linked to contemporary populations and standardized. The variable takes value 0 for bilateral descent and 1 otherwise (i.e., patrilineal, matrilineal, duolateral, quasi-lineage, and ambilineal descent). Source: Ethnographic Atlas (Murdock, 1967; Kirby et al., 2016).
Community organization	The variable is created based on entry EA015, then linked to contemporary populations and standardized. The variable takes value 1 if localized clans are present and/or if community endogamy exists, and takes value 0 if both are absent (i.e., agamous communities without localized clans and exogamous communities without clan structure). Source: Ethnographic Atlas (Murdock, 1967; Kirby et al., 2016).

KII	Following Schulz et al. (2019), we standardize the five sub-indicators of Kinship Intensity Index: cousin marriage preference, Polygamy, Co-residence of extended families, Lineage organization, Community organization. Then we take the average of the five standardized sub-indicators.
Subsistence variables (gathering, hunting, fishing, animal husbandry, and agriculture)	The data is linked to contemporary populations using entries EA001-EA005 of the Ethnographic Atlas. The five variables measure the fraction of a population's economic subsistence that depends on gathering, hunting, fishing, animal husbandry, and agriculture, respectively. Each entry takes the values 0 to 9 respectively for 0–5%, 6–15%, 16–25%, 26–35%, 36–45%, 46–55%, 56–65%, 66–75%, 76–85%, 86–100% dependence on the activity. We normalized the variables separately for each population so that they sum to 100% for each population. Source: Ethnographic Atlas (Murdock, 1967; Kirby et al., 2016).
Settlement complexity	The data is linked to contemporary populations using entry EA030. The variable classifies "settlement patterns" in the following categories: 1- nomadic; 2- seminomadic; 3- semisedentary; 4- impermanent; 5- dispersed homesteads; 6- hamlets; 7- village/town; 8- complex permanent. Source: Ethnographic Atlas (Murdock, 1967; Kirby et al., 2016).
Political hierarchies	The data is linked to contemporary populations using entry EA033 of the Ethnographic Atlas. The variable classifies "jurisdictional hierarchy beyond local community" in the following categories: 1- acephalous (e.g., autonomous bands and villages); 2- one level (e.g., petty chiefdoms); 3- two levels (e.g., larger chiefdoms); 4- three levels (e.g., states); 5- four levels (e.g., large states). Source: Ethnographic Atlas (Murdock, 1967; Kirby et al., 2016).
Migratory distance from Addis Ababa	The potential minimum travel time (on land only, and measured in months of travel) from Addis Ababa to the centroid of an ethno-lingustic group. Centroids of ethno-linguistic groups are defined using polygons provided by World Language Mapping System (WLMS 19th) for all languages of the world as defined by the Ethnologue 16th (Lewis, 2009). The raw data for travel time on land (Human Mobility Index) is defined for 1 km $\times$ 1 km cells. Whenever two pieces of land are disconnected by waters, we connect them manually in the closest linear distance using values from adjacent cells. Source: Özak (2018), Human Mobility Index (HMI).
Average inbreeding coefficient ($\overline{F_{ROH}}$)	Average inbreeding coefficient computed across the Human Origins (HO) individuals matched to each ethnicity. Individual inbreeding coefficients were computed using the ROHgen2 software pipeline developed by the ROHgen consortium (Clark et al., 2019). Source: computed using the HO data for this paper; see Appendix C for details.

Mean regional pairwise F_{ST}	Mean regional pairwise F_{ST} was first computed for each Human Origins (HO) population with at least five individuals, as the average of the pairwise F_{ST} between that population and all other populations in the same region with at least eight individuals in the (QCed) data. Then, each HO individual was assigned their HO population's mean regional pairwise F_{ST} estimate, and each Ethnologue ethnicity's mean regional pairwise F_{ST} was computed by taking the average its matched individuals. Source: computed using the HO data for this paper; see Appendix C for details.
Expected heterozygosity	For each Human Origins (HO) population j with at least five individuals, expected heterozygosity was computed for each SNP i using Nei and Roychoudhury's formula (Nei and Roychoudhury, 1974); the HO population j's expected heterozygosity was then estimated by summing up the estimated heterozygosities across all SNPs. Then, each HO individual was assigned their HO population's expected heterozygosity estimate, and each Ethnologue ethnicity's expected heterozygosity was computed by taking the average across its matched individuals. Source: computed using the HO data for this paper; see Appendix C for details.
Top 20 PCs	The top 20 principal components (PCs) of the genotypic data (i.e., of the $N \times N$ matrix with the entry in row i and column j equal to the correlation between individuals i and j's SNP data) were computed for each Human Origins (HO) individual. For each Ethnologue ethnicity, the mean of each PC was then computed across the ethnicity's matched individuals. Source: computed using the HO data for this paper; see Appendix C for details.

PRELIMINARY DRAFT: DO NOT CIRCULATE OR CITE

Region-level variables: **Variable name**	**Description**
Regional GDP per capita	Gross domestic product per capita in the region (in constant 2005 PPP dollars). For each country, regional GDP per capita is scaled so that their population-weighted sum equals the value of Gross Domestic Product reported in Penn World Tables or, when unavailable, World Development Indicators. Similarly, for each country, the regional population values are adjusted so that their sum equals the country-level analog in World Development Indicators. Source: Gennaioli et al. (2014)
Capital is in region	Dummy equal to 1 if the region contains a national capital, 0 otherwise, using ESRI World Cities: `http://www.esri.com/data/data-maps`. Source: Gennaioli et al. (2014)
Years of education	The average years of schooling from primary school onward for the population aged 15 years or older. To make levels of educational attainment comparable across countries, educational statistics are translated into the International Standard Classification of Education (ISCED) standard and use UNESCO data on the duration of school levels in each country for the year for which we have educational attainment data. Eurostat aggregates data for ISCED levels 0-2 and we assign such observations an ISCED level 1. Following Barro and Lee (1993): (1) zero years of schooling are assigned to ISCED level 0 (i.e., preprimary); (2) zero years of additional schooling are assigned to (a) ISCED level 4 (i.e., vocational), and (b) ISCED level 6 (i.e., post-graduate); and (3) 4 years of additional schooling are assigned to ISCED level 5 (i.e., graduate). Since regional data is not available for all countries, unlike Barro and Lee (1993), zero years of additional schooling are assigned: (a) to all incomplete levels; and (b) to ISCED level 2 (i.e., lower secondary). Thus, the average years of schooling in a region is calculated as: (1) the product of the fraction of people whose highest attainment level is ISCED 1 or 2 and the duration of ISCED 1; plus (2) the product of the fraction of people whose highest attainment level is ISCED 3 or 4 and the cumulative duration of ISCED 3; plus (3) the product of the fraction of people whose highest attainment level is ISCED 5 or 6 and the sum of the cumulative duration of ISCED 3 plus 4 years. See Gennaioli et al. (2014)'s online data appendix for sources and time periods. Source: Gennaioli et al. (2014)

Oil and gas production	Cumulative oil, gas and liquid natural gas production from the time production began to 2000. For onshore oil and gas, we calculated the production by region by allocating oil production to regions based on the fraction of the petroleum assessment areas within the region. Offshore assessment areas that are closer at all points to countries not included in the dataset than to countries included are removed. Offshore assessment areas that are in the area of countries within the dataset and countries not in the dataset are clipped at a distance of 100 km from the regions in the dataset. The assessment fields were then converted to a raster layer containing the cumulative production values in each cell, and the cells were allocated to regions based on the closest region. Oil and liquid natural gas were collected in millions of barrels. Gas was collected in billions of cubic feet and divided by 6 to convert to millions of barrels of oil equivalents. The datasets come from USGS World Petroleum Assessment Data. Source: Gennaioli et al. (2014)
Geographic variables	We aggregate the the pixel-level variables and data to region-level by taking the mean of constituent pixels. Source: Gennaioli et al. (2014)

PRELIMINARY DRAFT: DO NOT CIRCULATE OR CITE

Country-level variables: **Variable name**	**Description**
Openness	Following Gennaioli et al. (2014), we calculated the sum of exports and imports as a share of GDP. Source: Penn World Tables.
Article per million	Following Gennaioli et al. (2014), we use number of scientific and technical journal articles and population from the World Bank to generate the variables. The variable is calculated as the average from 2000 to 2018. Source: The World Bank
Patents per million	The variable is produced by Economist Intelligence Unit (2007, 2009). Source: Gorodnichenko and Roland (2016)
Expropriation risk	The variable is provided by International Country Risk Guide. Risk of "outright confiscation and forced nationalization" of property. This variable ranges from 0 to 10 where higher values indicate a lower probability of expropriation. This variable is calculated as the average from 1982 through 1997. Source: Gennaioli et al. (2013)
Institutional quality	The variable is generated based on World Bank's Enterprise Surveys. Latent variable of: (1) (minus) Informal payments; (2) (minus) Ln(tax days); (3) (minus) Ln(days without electricity); (4) (minus) Security costs; (5) (minus) Access to land, (6) (minus) Access to finance; (7) Government predictability; and (8) (minus) Doing Business percentile rank. Higher values indicate better institutions. Source: Gennaioli et al. (2013)
CPI	Following Gennaioli et al. (2013), we use Corruption Perception Index as a measure of institutional quality. CPI ranges from 0 to 100 where lower values indicate a higher corruption. Source: Transparency International
Blood donations	Voluntary blood donations per 1,000 inhabitants is taken from the WHO Global Status on Blood Safety and Availability 2016. The report contains data for the years 2011, 2012, and 2013. Following Schulz et al. (2019), we use the averages across these years. When data for a year is missing for a country, the indicator is based on the non-missing years. In about a third of the countries, not all blood centers are covered. In these cases, we did the following: The WHO report states the estimated percentage of blood donations covered; we calculated the total amount of blood donated based on those estimates. In the non-fully covered countries, the coverage is still reasonably high: 60% of those countries have a coverage above 75%. The WHO report gives further information on the types of donations: (i) voluntary non-remunerated donations, (ii) family/replacement donations, (iii) paid donations, or (iv) other. Our main variable of interest is voluntary non-remunerated donations per 1,000 inhabitants. To calculate per capita values, we divided the number of voluntary non-remunerated donations by the World Bank's population estimates (per 1000) for the year 2012. Source: WHO Global Status on Blood Safety and Availability 2016

PRELIMINARY DRAFT: DO NOT CIRCULATE OR CITE

Trust	The percentage of respondents in the country who believe that most people can generally be trusted. Data comes from World Values Survey. The variable takes the most recent available year collected by Gennaioli et al. (2013), ranging from 1980 through 2005. Source: Gennaioli et al. (2013)

A.2 Matching data

This Appendix section provides more detail about the procedures we used to match the various datasets we analyzed. At a high level, we matched ethnographic variables from the EA and genetic variables from the HO dataset to languages from the Ethnologue; then, we matched the Ethnologue languages to geographic pixels; finally, for the analyses at the region or country level, we collapsed the resulting pixel-level data to regions or countries.

Matching ethnographic and genetic variables to the Ethnologue languages

As we describe in the main text, to match the KII and other EA-derived variables to the pixel-level data, we first matched EA societies to contemporary languages from the 23rd edition of the Ethnologue (Gordon, 2005; Lewis, 2009). We employed two different matching methods. With the language-tree mapping method, the vast majority of the 5,756 Ethnologue ethnicities are matched to an EA society for each variable. With the direct matching method, the 911 EA societies with non-missing KII data are matched to 1,254 ethnicities (some of which speak the same languages but are in different countries).

Matching to pixels

We used a shapefile provided by the World Language Mapping System (World GeoDatasets)[1] to match pixels to Ethnologue ethnicities. Of the 783,525 pixels that remain after applying the filters described in Section 3.1, 133,614 (~ 17%) could not be matched to any ethnicity (either because the pixel is unpopulated according to the Ethnologue or because Ethnologue data is missing).

For the pixel-level analyses, we applied two additional filters. We dropped 52,782 pixels (~ 8%) that are matched to more than one ethnicity, and we dropped a further 104,965 (~ 18%) pixels that fall on the boundaries of an ethnicity's polygon or that were matched to an ethnicity with a very small polygon comprising less than five pixels.

When matching EA data to pixels, with the language-tree matching method we dropped a further 3,606 pixels due to missing data for a KII indicator, thus leaving 488,558 pixels located in the homelands of 2,352 ethnicities (which account for ~ 52% of the world population) around the world. The direct matching method leaves 377,656 pixels with nonmissing KII data and located in the homelands of 713 ethnicities (which account for ~ 38% of the world population). And matching the HO data to pixels leaves 281,177 pixels located in the homelands of 245 ethnicities.

Matching to regions and countries

To match pixel-level data to subnational regions or countries, we collapsed the pixel data—along with the ethnographic variables already matched to that data using either matching method—to the regions or countries. We did not apply here the two additional filters described just above for the pixel-level analyses, nor did we apply the filters listed in Section **??** to the pixel data prior to collapsing it, since these filters are only needed for the nighttime luminosity data. Specifically, to collapse the data for each ethnographic variable, we computed the population-weighted mean of the variable across the regions' or countries' pixels. For pixels matched to more than one Ethnologue language, we took the simple average of the EA variable across each pixel's languages. For variables defined at the pixel level, such as the geographic controls, we proceeded analogously, except that we took the simple (instead of the population-weighted) mean of each variable across each region's or county's pixels.

Finally, we dropped regions or countries for which the pixels with nonmissing KII data

[1]The shapefile is available at worldgeodatasets.com/language

account for less than 75% of the population. With the language-tree matching method, this left 1452 regions in 83 countries for the region-level analyses with the Gennaioli et al. (2014) data; with the direct matching method, this left 866 regions in 60 countries.

B Additional graphs and tables

B.1 Additional graphs and tables for Section 3 (Data)

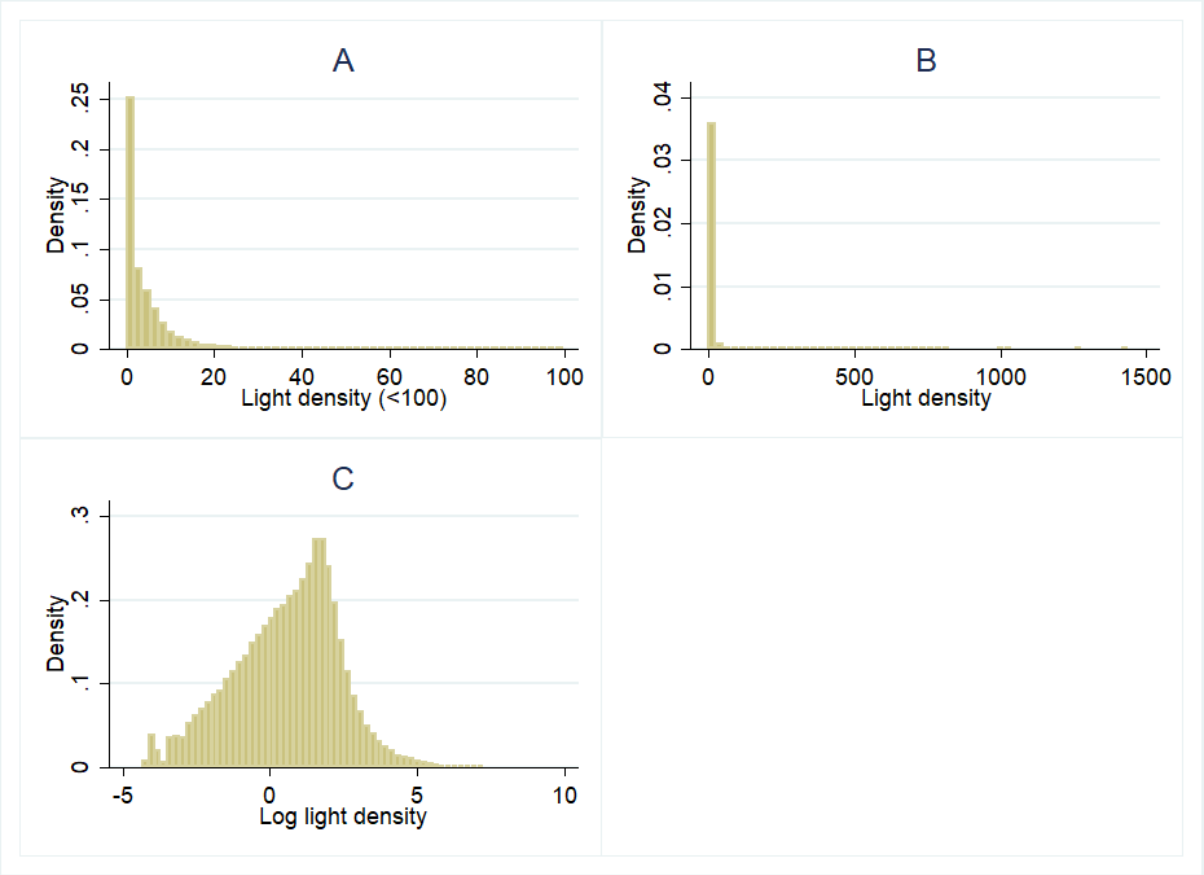

Figure B.1.1: Histograms of light and log nighttime luminosity for the pixels in our sample (after applying the filters described in Section 3.1), excluding the pixels with the lowest nonzero value (i.e., 0.013; these represent ~33% of the 783,525 pixels in the sample). Panels A shows an histogram for the subset of these pixels with luminosity less than 100; Panel B shows the same histogram but for all these pixels; and Panel C shows an histogram of log luminosity, also for all these pixels.

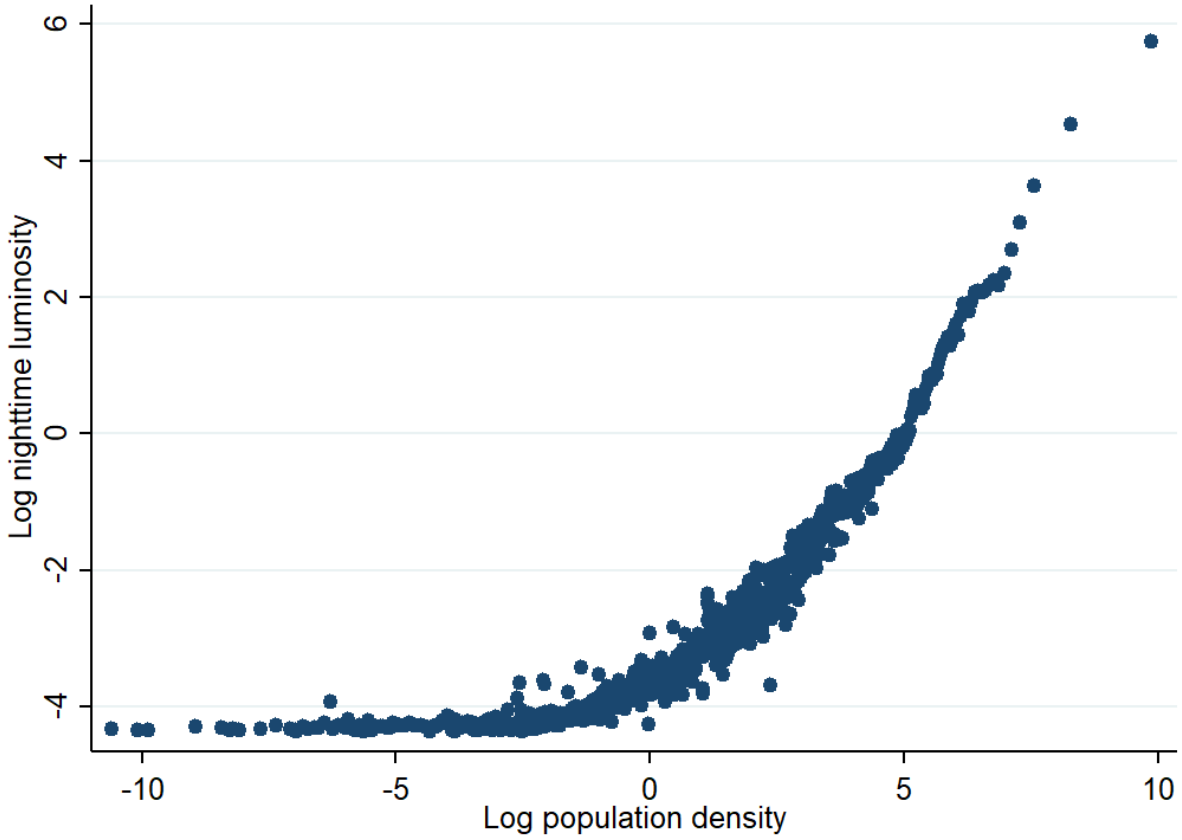

Figure B.1.2: Binned scatterplot (with one bin for every 1,000 observations) of the relationship between log nighttime luminosity and log population density across the 783,535 pixels in our sample (after applying the filters described in Section 3.1). In the analyses reported in the paper, unlike for this figure, we recoded to 1 the population density of pixels whose original population density was less than 1 person per square kilometer.

	KII KII	Cousin marriage preference	Polygyny	Co-residence of extended family	Lineage organization organization	Community organization

Notes: Robustness check with respect to population density. The relationship between the KII and light density holds across different ranges of population density.

C Computing the inbreeding coefficient and other variables in the Human Origins (HO) dataset

To obtain a contemporaneous, on-the-ground measure of kinship intensity, we analyzed genetic data from the Human Origins (HO) dataset from the David Reich Lab. HO contains genetic data on thousands of present-day and ancient individuals from populations around the world. We used the genetic data to compute the average inbreeding coefficient—which we use in our analyses as a proxy for cousin marriage rates—and other control variables for each population.

This appendix describes HO (C.1) and the matching procedure we employed to match the HO individuals and populations to Ethnologue ethnicities (C.2); provides some background on key genetics concepts (C.3); summarizes the quality control (QC) filters that were applied to the HO data before the data was analyzed (C.4); provides an overview of the variables we computed using the HO data (C.5); describes the methods we employed to compute the inbreeding coefficient (C.6) and other control variables (C.7, C.8, C.9) using the HO individuals genetic data; and reports summary statistics for the variables we computed (C.10).

C.1 The Human Origins dataset

We obtained a non-public version of the Human Origins (HO) dataset (Reich Lab (2020)) from the David Reich Lab on February 17, 2020. The HO version we obtained contains genetic data on 13,183 individuals, including 9,460 present-day individuals and 3,723 ancient individuals who lived between $\sim 88,000$ BCE and $\sim$ 1900 CE. It is a compiled dataset that includes individuals from many published studies and from many populations around the world (including Jeong et al. (2019); Lazaridis et al. (2016), Lazaridis et al. (2014); Lipson et al. (2018); Nakatsuka et al. (2017); Pickrell et al. (2012)).

We only include a subset of 4,756 present-day (i.e., non-ancient) individuals who have been genotyped on the Affymetrix Human Origin array in our analyses. These individuals were genotyped at a set of 597,573 genetic variants called single nucleotide polymorphisms (SNPs).

C.2 Matching the HO's populations to Ethnologue's ethnolinguistic groups (ethnicities)

As we further describe below, the subset of the HO we used in our analyses contains 4,756 individuals in 435 populations.[2] For each individual, HO has data on the individual's population, country, latitude, longitude, and in some cases on the individual's city or region. HO also lists the original publication from which each individual's data comes from, and some original publications include the language ISO code of the individual's ethnicity. We used this information, as well as various linguistic resources, Wikipedia entries, and an Ethnologue shapefile, to match each HO population to one of the Ethnologue's 6427 languages (which constitute 7,651 ethnicity-country combinations (what we call ethnicities).

As a first step, we conducted a many-to-one match to match each of the 435 HO populations to a single Ethnologue ethnicity in the HO population's country, and then dropped Ethnologue ethnicities that contain less than five individuals. This step resulted in 313 distinct Ethnologue

[2]We use the term "HO population" to describe the group identifier included for each individual in the HO dataset under the heading "Group Label", but the terms "ethno-linguistic group" or "ethnicity" could also apply in many cases.

ethnicities in our data. As a second step, we conducted a many-to-one match to match each of the 313 Ethnologue ethnicities to other ethnicities that speak the same Ethnologue language but are located in surrounding countries. This second step resulted in 551 distinct Ethnologue ethnicities in our data. The combination of steps 1 and 2 amounts to a many-to-many match from the 435 HO populations to 551 Ethnologue ethnicities.

Some of the variables we computed (the inbreeding coefficient and the top principal components (PCs)) were computed at the individual level and then averaged across the individuals in each Ethnologue ethnicity. Other variables (mean regional pairwise genetic distance and expected heterozygosity) were first computed for each HO population, following which each individual was assigned their HO population's value for each variable, which was then averaged across the individuals in each Ethnologue ethnicity.

Though we matched the HO data to 551 Ethnologue ethnicities, we note that the analyses with the inbreeding coefficient reported in the main text only used subsets of these 545 ethnicities. The analysis of the relationship between the inbreeding coefficient and cousin marriage preferences only used the 416 Ethnologue ethnicities with eight or more HO individuals; our analysis of the relationship between the inbreeding coefficient and nighttime luminosity, only used 245 of these 416 ethnicities that could be matched to a pixel that was not dropped from the data because of the filters we applied to the pixels (and which we describe in the main text).

C.3 Genetics background

We provide here a brief overview of some of the core genetic concepts needed to follow the remainder of this appendix. Other specific concepts are introduced below as needed. For a more detailed overview, see Beauchamp et al. (2011).

Humans have 23 pairs of chromosomes: they inherit 23 copies of each chromosomes from their mother and another 23 from their father. The elementary building blocks of DNA are nucleotide pairs associated with the four bases A, C, T, and G.[3] The human genome consists of approximately three billion pairs of nucleotide pairs and the associated bases on the 23 pairs of chromosomes.

Any two humans share ~99.9% of their genomes. At the remaining ~0.1%, different genetic variants exist in the populations. Single nucleotide polymorphism (SNPs) are the most prevalent type of genetic variants and our analyses only rely on SNP data. There are typically exactly two possible variants – also called alleles – at a given SNP's location in the genome[4]. A SNP's minor allele frequency (MAF) is the fraction the variants in the population that are the rarer variant at that SNP's location.

Autosomes are chromosomes other than the sex (X or Y) chromosomes, and our analyses only use SNPs on the 22 pairs of autosomes. Non-autosomal variants are variants on the sex (X or Y) chromosomes and are not used in our analyses.

[3]To be precise, a nucleotide pair is associated with a pair of bases rather than with a single base. Here, we ignore these subtleties and will refer to a single base associated with a nucleotide pair. Due to the principle of complementarity, the base A is always paired with the base T, the base C is always paired with the base G, and vice-versa; for that reason, one can focus on only one of the two bases associated with a nucleotide pair.

[4]By definition, there must be at least two possible variants at a SNP's location (else this would not be a SNP). SNP with more than two variants do exist but are rare.

C.4 Description of baseline quality control (QC) filters applied

As is customary when working with genetic data, we applied a number of quality control (QC) filters to the HO data to ensure that the data we analyzed was of sufficiently high quality.[5]. To do so, we used PLINK v2.00a3 (Chang et al. (2015)), a software tool that is commonly used to work with genetic data.[6] Our QC procedure is similar to the one employed by Ochoa and Storey (2019).

We applied the following QC filters, in this order:

- Step 1: removed all variants that are not single nucleotide polymorphisms (SNPs), all non-autosomal variants, and all monomorphic SNPs.[7]
- Step 2: removed all ancient individuals and individuals who were not genotyped on the Affymetrix Human Origins array, all individuals flagged by the David Reich Lab as being outliers, all individuals who could not be mapped to an ethnicity in the Ethnologue (including all individuals in admixed populations, since the Ethnologue does not contain admixed populations), and all individuals who were not mapped to at least one ethnicity in the Ethnologue to which at least four other HO individuals were also mapped (i.e., we only kept Ethnologue ethnicities with at least five matched Human Origins individuals). This left 4,771 individuals.
- Step 3: removed variants with missing call rates greater than 0.03 (108,180 SNPs removed).[8]
- Step 4: removed individuals with missing genotype rates greater than 0.03 (15 individuals removed).[9]

Before any QC, there were 13,776 ancient and present-day individuals and 597,573 variants in the HO data. After the baseline QC filters above were applied, the data contained information on 484,944 SNPs and 4,756 present-day individuals (1008 females, 3,679 males, 69 unknown) in 435 HO populations.[10]

(As mentioned above, these 435 HO populations were matched to 551 Ethnologue ethnicities, but for the analyses with the inbreeding coefficient reported in the main text, we only used subsets of these 545 ethnicities.)

[5]For a good overview of the different types of QC filters typically applied when working with genetic data, see Price et al. (2006)

[6]We also used PLINK v1.90b6.17 for some calculations because some PLINK commands had not been incorporated yet into PLINK v2.00a3.

[7]Monomorphic SNPs are SNPs that show no variation across all individuals; the variables corresponding to these SNPs are thus constants and can't be used in our analyses.

[8]The missing call rate for a given SNP is equal to N_{miss}/N, where N_{miss} is the number of individuals missing data for that SNP and N is the total number of individuals in the dataset.

[9]The missing genotype rate for an individual is equal to M_{miss}/N, where M_{miss} is the number of SNPs that are missing calls for that individual, and M is the total number of SNPs in the dataset.

[10]We do not apply minor allele frequency (MAF) filters in our baseline QC (other than removing monomorphic SNPs). The reason why is that, for some calculations, MAF filters are applied after calculating MAF at the language level, but for other calculations, MAF filters are applied after calculating MAF using all individuals in the HO data. These MAF filters are described below. We also do not apply a Heidy-Weinberg Equilibrium (HWE) filter because this needs to be applied separately for each population, and we choose not to do this due to small population sizes.

C.5 Variables computed with the HO genetic data: Overview

Our goal is to infer consanguineous marriage practices from inbreeding coefficients, and therefore factors that affect the inbreeding coefficient but are unrelated to parental relatedness are possible confounders in our analyses. In addition to computing the inbreeding coefficient, we therefore compute several quantities that are correlated with it but unrelated to parental relatedness, and we include these quantities in our main regressions as controls. Thus, for each population, we use the HO genetic data to compute the following quantities:

- *Inbreeding coefficient*: Our main variable of interest is the inbreeding coefficient, denoted F, which is the probability that two alleles at any given location in an individual's genome are identical by descent (IBD) – i.e., that they were inherited from the same ancestor. We compute F at the individual level and then take the ethnicity average. F is a measure of the relatedness of ones' parents. Consider, for instance, the offspring of two first cousins, who share a common grandfather and a common grandmother. The probability that two alleles at a location in the offspring's genome comes from a common grandparent and thus are IBD can be calculated to be 0.0625; this is the offspring's inbreeding coefficient. By contrast, the inbreeding coefficient of the offspring of completely unrelated individuals is 0. We compute two measures of the inbreeding coefficient. The baseline measure we use in the empirical analyses in the paper is F_{ROH}, defined as the fraction of an individual's genome that is located in runs of homozygosity (ROH) that are longer than 1.5 Mb.[11] ROH are segments of the genome that are identical across the maternally and paternally inherited chromosomes and thus could be IBD, and ROH that are longer than 1.5 Mb in length are more likely to arise from inbreeding (Ceballos et al. (2018)). We also compute an alternative measure of the inbreeding coefficient, F_{SNP}, which we use in the Appendix to verify that our F_{ROH} estimates are reasonable.

- *Mean regional pairwise* F_{ST}: Following Pemberton and Rosenberg (2014), we estimate the degree of genetic isolation of a population using the average pairwise F_{ST} (genetic distance) between that population and all other populations in the same world geographic region with a post-baseline-QC sample size of at least 8 individuals.

- *Expected heterozygosity*: Controlling for a population's expected heterozygosity is especially important in our setting, since expected heterozygosity correlates negatively with population mean F (Pemberton and Rosenberg (2014)) and has been hypothesized to be related to economic development (Ashraf and Galor (2013)). Expected heterozygosity decreases with migratory distance from East Africa, consistent with a migration model that predicts increased genetic drift and decreased heterozygosity with increased distance from Africa (Ramachandran et al. (2005)). In our empirical analyses with our F_{ROH} estimates, we also control for migratory distance from East Africa.

- *The top 20 PCs of the genotype*: We compute the top 20 principal components (PCs) of the genotypic data[12] for each individual, and take the average value of each PC in each population. It has been shown that the top PCs are good proxies for the individuals' geographic origins and that including these as controls in regressions can help mitigate bias related to population stratification (Novembre et al. (2008); Price et al. (2006)).

Below, we discuss these quantities in more detail and describe how we computed them.

[11] A megabase (Mb) is a unit of physical distance in the genome; the entire genome is ~3,100 Mb in length.

[12] Specifically, we compute the 20 PCs of the $N \times N$ matrix with the entry in row i and column j equal to the correlation between individuals i and j's SNP data.

C.6 The inbreeding coefficient: background and estimation

Inbreeding occurs when related individuals mate and produce offspring. Related individuals share DNA from common ancestors, and thus inbreeding increases the probability that at a given location on a chromosome, their offspring inherits identical DNA segments from both parents (Ceballos et al. (2018)). For instance, first cousins share both a grandmother and a grandfather, and so some DNA segments which they inherited from the common grandmother or grandfather will be identical across their two genomes. As a result, if two first cousins mate and produce a child, then that child will have locations in their genome where they will have inherited identical DNA segments from their two cousin parents, coming originally from the same grandmother or grandfather. The two alleles at a such genomic location are said to be homozygous – since the two alleles at the location are identical – and identical-by-descent (IBD; or autozygous) – since they are identical and can be traced back to one common ancestor.

A common measure of one's level of inbreeding is the coefficient of inbreeding, denoted F. F measures the probability that two alleles at a location in the genome are IBD, and is also equal to the fraction of the genome that is IBD for a given individual. The expected value of an individual's F coefficient is equal to the coefficient of kinship, or one-half the coefficient of relationship, between his two parents. The latter is a measure of the relatedness between two individuals (the two parents, here). For example, the expected F coefficient of the offspring of two second-degree cousins is 0.015625, whereas it is 0.0625 for the offspring of first-degree cousins and 0.25 for the offspring of two siblings. Thus, F measures the degree to which an individuals' two parents were related.

Various methods have been developed to estimate F using an individual's molecular genetic data. Recent advances in genetic technology have led to the development of methods to identify continuous segments of homozygous alleles, known as runs of homozygosity (ROH), in individual genomes. Longer ROH are typically observed as a result of inbreeding (Ceballos et al. (2018)), and have been shown to correlate well with pedigree-based estimates of inbreeding (Kang et al. (2017); McQuillan et al. (2008); Pemberton and Rosenberg (2014)) and, as Sahoo et a. (2021) found and as we report in the main text, with population-level cousin marriage preferences.

However, ROH can arise in individuals for a variety of reasons unrelated to marital practices and kinship systems. For example, ROH and inbreeding coefficients are inflated in genetically isolated populations, since low effective population sizes can increase homozygosity (Pemberton and Rosenberg (2014)). In addition, inbreeding coefficients are highly correlated with expected heterozygosity and migratory distance from Africa (Pemberton and Rosenberg (2014)). In the main empirical analyses in the main text, we control for these and other variables.

C.6.1 Estimating F_{ROH}

Our main measure of inbreeding, denoted F_{ROH}, is the fraction of an individual's genome in runs of homozygosity (ROH) of at least 1.5 Mb in length (Clark et al. (2019)). This is the baseline measure used by the ROHgen consortium, a large consortium of research groups administering cohorts with genetic data that seeks to estimate the effect of inbreeding on various traits (Clark et al. (2019); Joshi (2015)). We estimate F_{ROH} for all individuals in the (post-baseline-QC) dataset using the ROHgen2 software pipeline developed by the ROHgen consortium (Clark et al. (2019)).

Shorter ROH are more likely to arise from population structure or lack of genetic diversity whereas longer ROH (e.g., ROH 1.5 Mb in length or longer) tend to arise from inbreeding (Ceballos et al. (2018); Kang et al. (2017); Pemberton et al. (2012); Sahoo et al. (2021)).

Using ROH that are at least 1.5 Mb long to compute F_{ROH} mitigates, but does not eliminate, concerns that an individual's homozygous alleles have arisen due to factors other than parental relatedness, such as low effective population size or decreased genetic diversity.

Formally, suppose an individual has n ROH greater than 1.5 Mb across their genome. For each of these ROH $i \in \{1, \ldots, n\}$, define l_i as the length (in Mb) of ROH i. F_{ROH} is defined as:

$$F_{ROH} = \sum_i \frac{l_i}{3Gb}$$

where the length of the autosomal genome is estimated at 3 Gb base pairs (i.e., 3,000 Mb; Clark et al. (2019)).

Let $\overline{F_{ROH}}$ denote the average F_{ROH} across the individuals in a population or ethnicity. We obtained estimates of $\overline{F_{ROH}}$ both for each Ethnologue ethnicity (for the main analyses in our paper) and for each HO population (for Supplementary Figures **??** and C.6.2 below in this Appendix).

Before calculating the inbreeding coefficient F_{ROH}, we applied one additional QC filter (in addition to the QC filters described above): following the ROHgen2 guidelines, we filtered out the SNPs with minor allele frequency (MAF) less than 0.05.[13] Filtering out SNPs with low MAF is important because including those SNPs may result in more ROH that are not due to marital practices. Ideally, we would calculate MAF for each population before filtering out low-MAF SNPs. However, due to data limitations and small population sizes for many populations, this was not possible. We thus calculated MAF using all (post-baseline-QC) individuals in the dataset before filtering out SNPs with MAF < 0.05. 369,741 autosomal SNPs were left after this step, and these were used to compute F_{ROH}.[14]

After we applied the MAF filter, we calculated F_{ROH} using the ROHgen2 pipeline (Clark et al. (2019)). The ROHgen2 pipeline calculates F_{ROH} using PLINK v2.00a3 (Chang et al. (2015)) with the following parameters: –homozyg-window-snp 50; –homozyg-snp 50; –homozyg-kb 1500; –homozyg-gap 1000; –homozyg-density 50; –homozyg-window-missing 5; –homozyg-window-het 1.These parameters have been previously shown to call ROH that mainly correspond to alleles that are identical-by-descent (IBD), mitigating concerns that measured ROH are due to chance arrangements of independent homozygous SNPs (Clark et al. (2019)). In addition, these parameters have been previously shown to be robust to genotyping array choice (Joshi (2015)).

Appendix Table C.6.1 shows summary statistics for F_{ROH} calculated across the individuals in each geographic region of the world.[15] As can be seen, F_{ROH} tends to be higher in regions

[13]There are typically two possible variants at a given SNP's location in the genome, and a SNP's MAF is the fraction the variants in the population that are the rarer variant at that SNP's location.

[14]Instead of using all individuals in the dataset to calculate MAF, we could have chosen to calculate MAF separately for each language family in the data. This is what we do for our calculations of F_{SNP} (see below). (The language families are higher-level language groupings from the Ethnologue; each Ethnologue ethnicity corresponds to a single language, which belongs to a language family. Populations in the same language family tend to be ethnically and thus genetically more similar to each other and thus should exhibit similar allele frequencies.) However, we chose not to use language families to calculate MAF prior to MAF filtering for our preferred estimate of F_{ROH} for the following two reasons. First, the correlation between F_{ROH} computed after MAF filtering using MAF calculated with all individuals and F_{ROH} computed after MAF filtering using MAF calculated separately for each language group is almost unity ($\hat{r} = 0.998$). The two methods of computing F_{ROH} thus yield nearly identical quantities. Second, computing allele frequencies using all individuals allows us to compute F_{ROH} for a few individuals that were not mapped to a language family.

[15]The geographic regions we use are from the United Nations' "M49 standard" (*Standard Country or Area Codes for Statistical Use (M49)*).

that are far from East Africa (such as the Americas and Melanesia), and lower in regions that are close to Africa (such as Northern and Sub-Saharan Africa). The reason for this is that, as mentioned above, F ecreases with expected heterozygosity, which in turn decreases with migratory distance from East Africa (Pemberton and Rosenberg (2014)). In the paper, the empirical analyses with our F_{ROH} estimates include controls for both migratory distance from East Africa and expected heterozygosity.

Appendix Table C.6.1. Summary statistics for F_{ROH} in each geographic region of the world.

Region	Mean	SD	Minimum	Maximum	IQR*
Latin America and the Caribbean	0.0598	0.0442	0.0080	0.2579	0.0537

Table C.6.1:

C.6.2 Estimating F_{SNP}

As a check to ensure that our calculation of F_{ROH} yielded reasonable estimates, we also computed estimates for another measure of inbreeding, F_{SNP}, and then compared the two sets of estimates. F_{SNP} calculates excessive homozygosity in an individual, where the excess is relative to the level of homozygosity one would expect in a population of randomly mating individuals. F_{SNP} can be strongly biased as an estimator of inbreeding due to factors other than inbreeding, such as population structure and small population size (Clark et al. (2019)), and we thus do not use F_{SNP} as the main estimator of inbreeding in our analyses. However, following Clark et al. (2019), we calculate F_{SNP} and compare our F_{SNP} and F_{ROH} estimates.

Thus, for each individual in our data we calculated F_{SNP}, defined as

$$F_{SNP} = \frac{O\left(HOM\right) - E(HOM)}{M - E(HOM)}, \tag{1}$$

where $O\left(HOM\right)$ is the observed number of homozygous SNPs and $E(HOM)$ is the expected number of homozygous SNPs in the individual's autosomal genome, and M is the number of non-missing genotyped SNPs on the individual's autosomes (Clark et al. (2019)). The expected number of homozygous SNPs is given by $E\left(HOM\right) = \sum_i \left[(p_i)^2 + (1-p_i)^2\right]$, where p_i is the MAF of SNP i,[16] and is equal to $M\left(1-\hat{H}\right)$, where $\left(1-\hat{H}\right)$ is expected homozygosity and $\hat{H}$ is expected heterozygosity (defined below).

We define $\overline{F_{SNP}}$ to be the average F_{SNP} across individuals in a population (this quantity is often denoted as F_{IS}). Populations in which consanguineous marriages are the main drivers

[16]This follows from the fact that, if mating is random (i.e., under Hardy-Weinberg equilibrium), the event in which an individual has only one copy of the rarer allele (and one copy of the more common allele) – i.e., is *not* homozygous – at SNP i follows a binomial distribution with two trials (corresponding to the two locations on the maternal and paternal chromosomes) and probability p_i. From this, the probability that an individual in a randomly mating population is homozygous at SNP i is $1 - 2p_i\left(1-p_i\right) = (p_i)^2 + (1-p_i)^2$.

of ROH have $\overline{F_{SNP}} \approx \overline{F_{ROH}}$, since inbreeding is the main driver of excessive homozygosity in these populations (Clark et al. (2019)).

We used a slightly different set of SNPs to calculate F_{SNP} compared to F_{ROH}. Prior to filtering out SNPs with MAF < 0.05, for F_{ROH} we calculated allele frequencies using all individuals in the data. In contrast, for F_{SNP} we calculated allele frequencies separately for each language family before filtering out SNPs with MAF < 0.05.

Though F_{SNP} is calculated for each individual, the formula uses expected homozygosity as an input. Ideally, we would have calculated expected homozygosity separately for each population in the data. However, due to the small sample sizes for many populations in HO, calculating expected homozygosity separately for each population leads to noisy estimates of F_{SNP}. We thus calculated expected homozygosity for each language family, because populations in the same language family tend to be ethnically and thus genetically more similar to each other and thus should exhibit similar expected homozygosities.We merged language families with fewer than 40 individuals together to eliminate small language families.

We calculated F_{SNP} using the ROHgen2 pipeline (Clark et al. (2019)). The ROHgen2 pipeline calculates F_{SNP} using PLINK's '–het' command. Although the ROHgen2 pipeline does not include the 'small-sample' flag with the '—het' command, we included the 'small-sample' flag for our calculations.

C.6.3 Diagnostic plots and quality checks

In **Figure C.6.1**, we display several histograms that are produced by the ROHgen2 pipeline, using individual-level estimates of F_{ROH} and F_{SNP}. The figure compares the distribution of F_{ROH} and F_{SNP} to the distribution of these variables in a sample population from the UK.[17] As can be seen, the distributions of F_{ROH} and F_{SNP} (denoted 'f_roh' and 'f_het' in the two bottom panels of the figure) in the sample UK population (in light blue) lie in the left tail of the distributions in HO (in pink).

Figure C.6.2 plots the inbreeding coefficients, with HO-population-level estimates of $\overline{F_{ROH}}$ on the y-axis and $\overline{F_{SNP}}$ on the x-axis. (We note that the empirical analyses in the main paper use Ethnologue-ethnicity level estimates of $\overline{F_{ROH}}$ rather than HO-population level estimates.)

As Panel A shows, populations in language groups with large sample sizes have a strong tendency to lie close to the 45-degree line in the figure. For populations with data points near the 45-degree line, $\overline{F_{SNP}} \approx \overline{F_{ROH}}$, which signifies that consanguinity is a main driver of excessive homozygosity for these populations (Clark et al. (2019)). However, populations in language groups with small samples sizes tend to lie to the left of the 45-degree line; the reason for that is that small sample sizes lead to a more sizeable downward bias in F_{SNP}, which skews data points to the left in the figure.[18] Populations to the right of the 45-degree line tend to be characterized by admixture, since admixture biases F_{SNP} upwards (Clark et al. (2019)).

In Panel B, we label several populations that are to the right of the 45-degree line. Three populations in Botswana— "Taa_East:Botswana" (label 400), "Taa_North:Botswana" (label 401), and "Taa_West:Botswana" (label 402)—are located noticeably to the right of the 45-degree line. These three populations are pooled in the "Niger-Congo" language family, and sufficient divergence from other populations in this group may explain the inflation of F_{SNP}

[17] While the set of SNPs we used to compute F_{ROH} in our main analyses is different than the one we used to compute F_{SNP}, for **Supplementary Figure A1**, for comparability, for each language family we used the exact same set of SNPs to compute F_{ROH} as the one we used to compute F_{SNP}.

[18] The reason for the downward bias is that in small samples, MAF ($\hat{p}_i$) is estimated with less precision, which by Jensen's inequality leads to a upward bias in estimates of $(p_i)^2 + (1 - p_i)^2$ and thus upward bias in estimates of $E(HOM)$ and downwards bias in estimates of F_{SNP}.

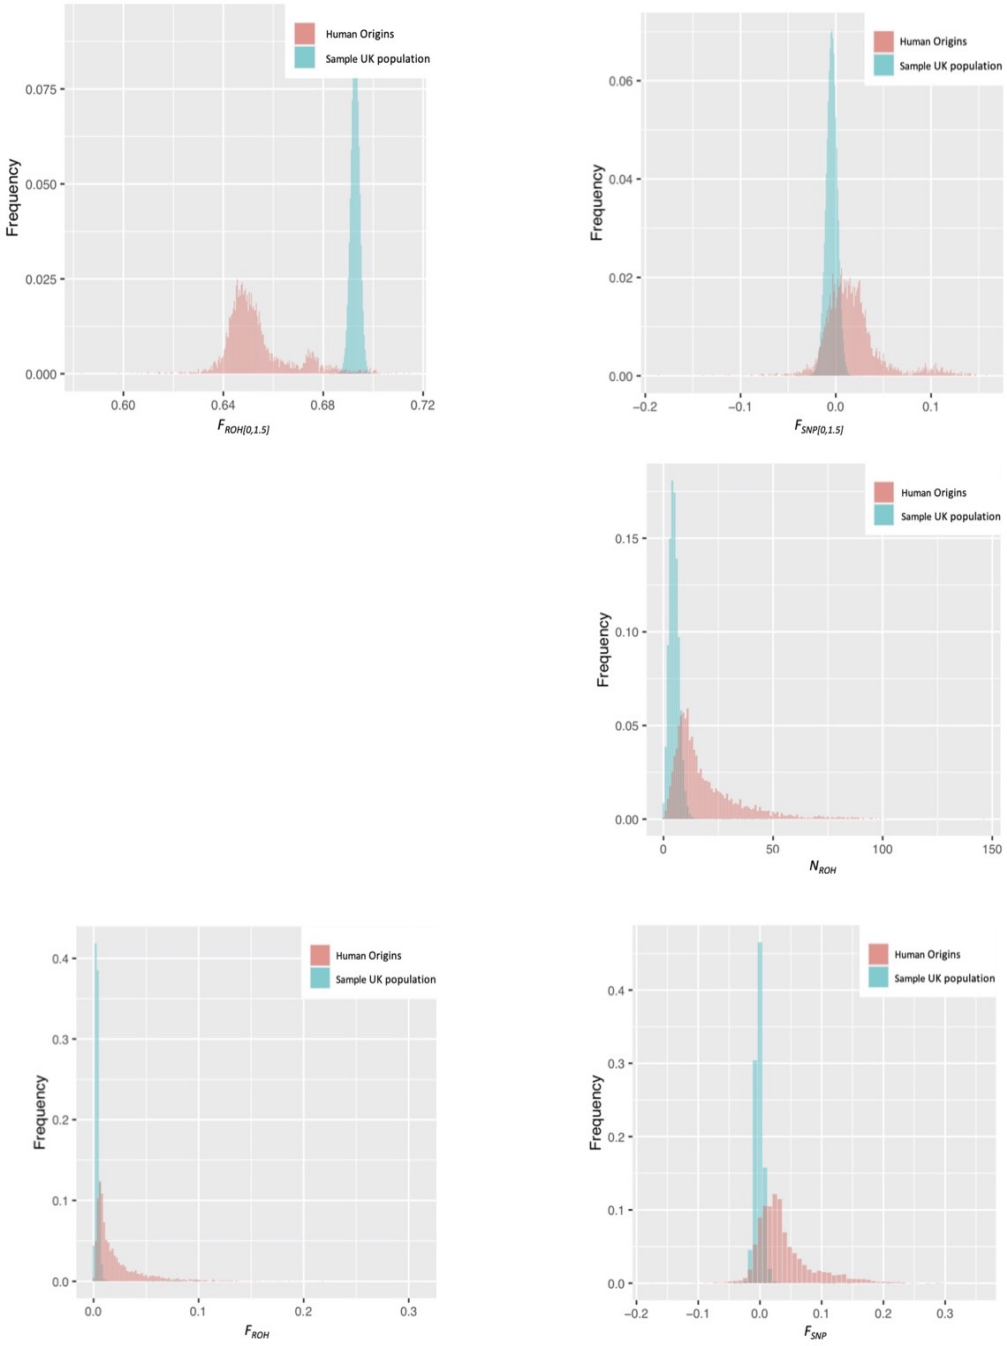

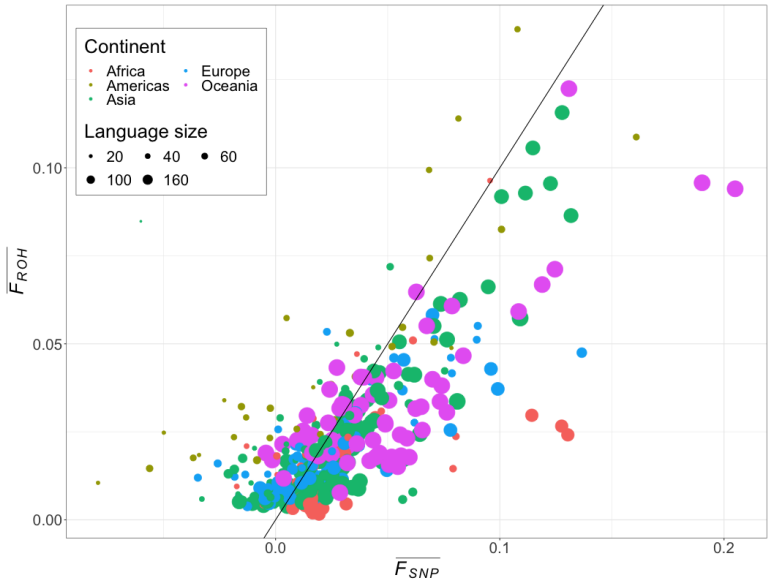

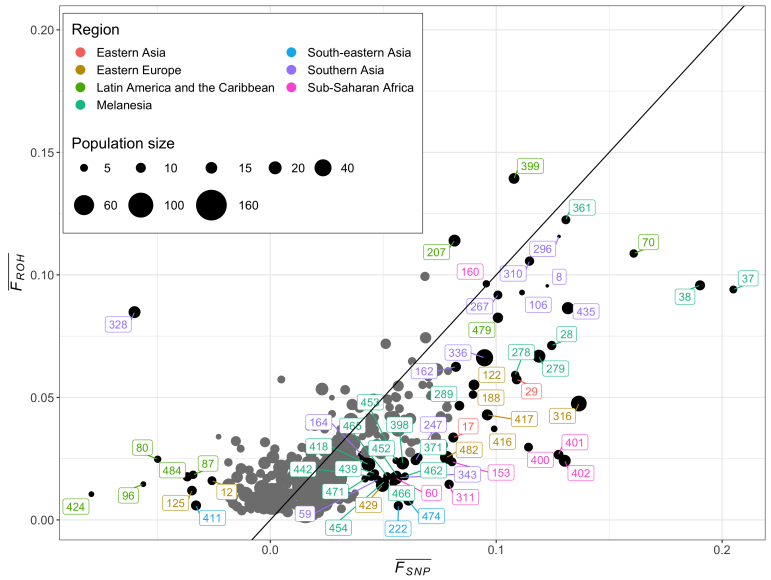

Figure C.6.1: This figure is produced by the ROHgen2 pipeline. It compares F_{ROH} and F_{SNP} in our data to those in a sample UK population. Note that F_{ROH} and F_{SNP} here are calculated using allele-frequency filters applied separately for each language language family. F_{ROH}, as described above, is the fraction of the autosomal genome in ROH longer than 1.5 Mb; $F_{ROH[0,1.5]}$ denotes the fraction of the autosome homozygous outside ROH. F_{SNP}, as described above, is calculated using all SNPs in the autosomal genome; $F_{SNP[0,1.5]}$ denotes F_{SNP} calculated in the autosomal genome outside ROH longer than 1.5 Mb; N_{ROH} denotes the count of ROH longer than 1.5 Mb.

(a)

(b)

Figure C.6.2: The two panels both display the mean F_{ROH} on the y-axis and mean F_{SNP} on the x-axis for each population. The solid black line in both panels is the 45-degree line. In Panel A, each circle is a population and the size of the circle corresponds to the number of individuals in each language family (after merging several language families with less than 40 individuals). In Panel B, the size of each circle corresponds to the number of individuals in each population. Several outliers are labeled in Panel B. Populations in lower right quadrant are labeled if ($\overline{F_{ROH}} \leq 0.0265$ and $\overline{F_{SNP}} \geq 0.04$) or ($\overline{F_{ROH}} > 0.0265$ and $\overline{F_{SNP}} \geq 0.08$). The list of populations corresponding to the numbers labeling the circles in Panel B is shown in **Appendix Table C.6.2**. '$\overline{F_{ROH}}$' denotes the population's mean F_{ROH}; '$\overline{F_{ROH}}$' denotes the population's mean F_{SNP}.

Table C.6.2: The table lists the populations corresponding to the numbers labeling the circles in Panel B of Figure **C.6.2.**

relative to F_{ROH} in these populations. A similar explanation likely explains why the populations "Baining_Malasait:Papua New Guinea" (label 37) and "Baining_Marabu:Papua New Guina" (label 38) from the "Austronesian (Melanesia)" language family are far to the right of the 45-degree line.

(We also note that, in principle, populations that appear in the North-West quadrant of the figure, with high $\overline{F_{ROH}}$ and low $\overline{F_{SNP}}$, would tend to be genetically isolated (Clark et al. (2019)). However, there is no population whose language family has a large sample size that is far to the left of the 45-degree line the figure.)

We conclude from this comparison exercise between our estimates of F_{ROH} and F_{SNP} that our estimates of F_{ROH} likely partly capture average levels of inbreeding across populations. This is consistent with the results of Sahoo et al. (2021) and with analyses we report in the main text.

C.7 Mean regional pairwise F_{ST}: background and estimation

Genetic isolation occurs when a population has little genetic mixing with other populations. In humans, this can occur due to geographical or cultural distance or taboos prohibiting mating with individuals from other populations. Genetic isolation is associated with reduced mate choice and thus with increased cryptic inbreeding, in which two parents may have a recent common ancestor in common by chance (and not due to a deliberate cultural practice of mating relatives) (Pemberton and Rosenberg (2014)).

F_{ST} is commonly used to quantify genetic distance, or genetic divergence between populations. Two populations with a low genetic distance will have similar distributions of alleles, and two genetically distant populations will have relatively large between-population differences and relatively small within-population differences (Pemberton and Rosenberg (2014)).

Following Pemberton and Rosenberg (2014), we proxy for genetic isolation for a given population by first calculating the mean of the population's pairwise F_{ST} with other populations in the same geographic region of the world.[19] Pemberton and Rosenberg (2014) showed that mean regional pairwise F_{ST} correlates positively with ROH (Pemberton and Rosenberg (2014)).

Our estimator of F_{ST} is the Weir and Cockerham (1984) estimator. We only calculated pairwise F_{ST} for two HO populations in a region if both populations have at least five individuals. After excluding HO populations with less than five individuals, we obtained 371 populations that are mapped to 545 Ethnologue ethnicities.[20] For each of these 371 populations, we then calculated the mean regional pairwise F_{ST} as the average pairwise F_{ST} across all other populations in the same region that have at least eight individuals (Thus, while we computed the mean regional pairwise F_{ST} for all HO populations with at least five individuals, we only used other populations in the same region with at least eight individuals to compute each population's mean regional pairwise F_{ST}).

[19]The world geographic regions we use are again those from the United Nations' "M49 standard" (*Standard Country or Area Codes for Statistical Use (M49)*). We merged Polynesia and Melanesia for this analysis because the Polynesia region only had 6 individuals.

[20]Note that we have only 371 HO populations here, while the main sample we obtained after applying our baseline QC filters as described in Section C.4) comprised 435 HO populations. These numbers differ because in Section C.4), we dropped individuals who belong to *Ethnologue ethnicities* with fewer than 5 individuals, whereas here when calculating F_{ST} we apply an additional filter and drop individuals who belong to *HO populations* with fewer than 5 individuals.

After calculating the mean regional pairwise F_{ST} for each of the 371 HO populations, we assigned each HO individual their HO population's mean regional pairwise F_{ST} estimate, and then obtained estimates of the mean regional pairwise F_{ST} for each of the 545 Ethnologue ethnicities by taking the average across the ethnicity's individuals (As mentioned above, for the analyses reported in the main text, of the relationships between F_{ROH} and cousin marriage preferences analyses and between nighttime luminosity and F_{ROH}, we only used subsets of the 545 ethnicities).

To compute pairwise F_{ST} for any two populations, we took the set of SNPs and individuals that passed our baseline QC filters and removed all SNPs with MAF < 0.05. That step removed 115,203 SNPs, resulting in 369,741 remaining SNPs in the data. We then used PLINK to LD prune the remaining SNPs. We used PLINK's '–indep-pairwise' command to LD prune the SNPs, with window-size 1E6 kb, step-size 50 kb, r^2 threshold of 0.1. This left a total of 50,739 quasi-independent SNPs for the F_{ST} calculations. (As mentioned below, we used that same set of SNPs to compute the top 20 Principal Components (PCs) in the HO data.) We calculated pairwise F_{ST} using PLINK's '–fst' and then used the reported weighted global mean as the pairwise F_{ST}.

C.8 Expected heterozygosity: background and estimation

Another correlate of F_{ROH} is expected heterozygosity (Pemberton and Rosenberg (2014)). Expected heterozygosity is a measure of genetic diversity in a population; it is defined as the probability that two randomly selected individuals from a population have different alleles at a randomly selected location on one chromosome in the genome. Equivalently, if people mate at random (i.e., under Hardy-Weinberg equilibrium), expected heterozygosity is the probability that the two alleles one has at a randomly selected location in the genome are identical across one's two chromosomes.

ROH and F_{ROH} are negatively correlated with expected heterozygosity across populations (Pemberton and Rosenberg (2014)). This is because, if there are relatively more homozygotes in the population, individuals will tend to exhibit more ROH, even in the absence of consanguineous cultural practices. Consider the following simple example, where there is no genetic variation in the population and all individuals are therefore fully homozygous. If we attempt to infer autozygosity by counting ROH in a sample of individuals from the population, we will incorrectly conclude that the population is fully inbred.

Expected heterozygosity has been shown to be highly correlated with migratory distance from Africa (Ramachandran et al. (2005)). This relationship is consistent with a model in which, as human beings migrated outside the "cradle of humankind" in East Africa and spread across the globe, the individuals who migrated to new colonies only carried with them a subset of the genetic diversity of the parent colony (Ramachandran et al. (2005)). This is known as the "serial founder effect."[21]

Expected heterozygosity has also been found to be (non-linearly) associated with economic development (Ashraf and Galor (2013)), though some have questioned the robustness of these

[21] Another factor that may contribute to this relationship is ascertainment bias in genotyping microarrays (Patterson et al. (2012)). Only a subset of SNPs are genotyped in microarrays, and SNPs with a higher MAF in a reference population are typically favored. For instance, if the reference population is European, then the inclusion of SNPs with high MAF among Europeans on the genotyping array may lead to an upward bias in estimates of expected heterozygosity and downward bias in estimates of ROH and F among Europeans vs. among other populations. (By definition, MAF are in the interval [0, 0.5], so higher MAF are closer to 0.5.) The Affymetrix Human Origins array used for the dataset we analyze, HO, has been specifically designed to mitigate ascertainment bias (Patterson et al. (2012)), but ascertainment bias may nonetheless be a concern.

results (Rosenberg and Kang (2015)). Thus, it is important to control for expected heterozygosity (and other confounders) in order to confidently use F_{ROH} as a proxy for consanguineous unions, especially in our analyses of the relationship between F_{ROH} and economic development.

As we did to estimate mean regional pairwise F_{ST}, we only computed expected heterozygosity for HO populations that have at least five individuals. After excluding populations with less than five individuals, we obtained 371 populations that are mapped to 545 Ethnologue ethnicities. After calculating expected heterozygosity (as described below) for each of the 371 HO populations, we assigned each HO individual their HO population's expected heterozygosity estimate, and then obtained estimates of the expected heterozygosity for each of the 545 Ethnologue ethnicities by taking the average across the ethnicity's individuals. (As mentioned above, for the analyses with $\overline{F_{ROH}}$ reported in the main text, we only used subsets of these 545 ethnicities.)

We calculated expected heterozygosity for each SNP i and each HO population j using Nei and Roychoudhury's formula for expected heterozygosity (Nei and Roychoudhury (1974))[22]:

$$\hat{h}_{ij} = \frac{n_j}{n_j - 1}\left(1 - (p_{ij})^2 + \left(1 - p_{ij}\right)^2\right), \tag{2}$$

where p_{ij} is the minor allele frequency (MAF) of SNP i in population j and n_j is the number of alleles in the data for population j.[23] We calculated expected heterozygosity for population j by summing up the $\hat{h}_{ij}$ across all SNPs:

$$\hat{H}_j = \sum_i \hat{h}_{ij}. \tag{3}$$

Before calculating expected heterozygosity for each population, we took the SNPs that passed our baseline QC filters and removed all SNPs with MAF < 0.05 and missing call rates > 0.01. Note that we calculated MAF here using all individuals in the HO data that passed our baseline QC. We applied a more stringent missing call rate threshold of 0.01 (compared to 0.03, which is the threshold in our baseline QC) to reduce the number of SNPs that have very few individuals in a population with non-missing genotypes for those SNPs.

After applying those QC filters, we used PLINK to LD prune the remaining SNPs (i.e., to obtain a subset of SNPs that are no more than weakly correlated with one another in the genome). We used PLINK's '–indep-pairwise' to LD prune the SNPs, with window-size 1E6 kb, step-size 50 kb, r^2 threshold of 0.1. After LD pruning, we obtained 50,383 quasi-independent SNPs.

We then removed all SNPs that had at least one population with strictly less than four non-missing alleles for that SNP. This resulted in an additional four SNPs being removed. Therefore, we had 50,379 SNPs for our expected heterozygosity calculations.[24]

[22] Nei and Roychoudhury's method (1974) yields unbiased estimates of expected heterozygosity only in samples with no inbred or related individuals (DeGiorgio and Rosenberg (2009)). Here, our F_{ROH} estimates clearly suggest inbreeding is present in some populations and some individuals are likely related, so our estimates of $\hat{H}_j$ are not unbiased. We expect this to generate no more than a small bias in our the empirical analyses we report in the paper.

[23] Thus, if there are N_j individuals in population j in the dataset and if there are no missing observations for that SNP, $n_j = 2N_j$.

[24] Note that we also calculated expected heterozygosity after removing all SNPs that had at least one population with strictly less than eight non-missing alleles (instead of less than four non-missing alleles). This removed 892 SNPs. The estimated correlation between the estimates of expected heterozygosity obtained using these two different sets of SNPs is unity.

To obtain the quantities necessary to calculate expected heterozygosity, we used PLINK's "–freq" which reports the minor allele frequencies and number of non-missing alleles for each SNP.[25]

C.9 The top 20 Principal Components (PCs): background and estimation

In order to control for population structure, we also calculated the top 20 principal components (PCs) of the genotypic data for each individual. For each Ethnologue ethnicity, we then obtained the mean of each PC by taking the average across the ethnicity's individuals.

The top PCs have been shown to correlate strongly with ancestry (Novembre et al. (2008); Price et al. (2006)). Controlling for the top PCs is standard in analyses with individual-level genetic data and can mitigate bias due to population stratification.[26] Population stratification could pose a threat to our empirical analyses since allele frequencies affect homozygosity and thus F_{ROH}.

To compute the top 20 PCs, we used PLINK's "−−pca" command with the same set of 50,739 SNPs that we used to compute the pairwise F_{ST} between populations (see Section C.8).

C.10 Summary statistics

Table C6 reports the mean, standard deviation, minimum, and maximum for the core variables we computed with the genetic data: the inbreeding coefficient ($\overline{F_{ROH}}$), mean regional pairwise F_{ST}, and expected heterozygosity. These summary statistics were computed across the 416 Ethnologue ethnicities with eight or more HO individuals (and which we used in the analysis, reported in the main text, of the relationship between the inbreeding coefficient and cousin marriage preferences). The Table does not report these summary statistics for the top 20 PCs, which are all normalized to have a mean of zero and unit variance.

[25] Note that, unlike for the estimation of expected homozygosity (which is equal to one minus expected heterozygosity) when computing F_{SNP}, which we computed at the language level using PLINK's "–het" command with the 'small-sample' flag, here we used Nei & Roychoudhury's formula to compute population-level expected heterozygosity. The main reason for the difference is that PLINK's "−−het" command computes expected heterozygosity at the individual level using each individual's nonmissing SNPs, and here we wanted to use the same set of SNPs to compute expected heterozygosity for all populations.

[26] Population stratification refers to systematic differences in allele frequencies that correlate across populations with cultural or environmental differences that causally impact variables of interest (Hamer (2000)).
