Relative Price Shocks and Inflation*

This Version: February 2024

Abstract

Inflation is determined by interaction between real factors and monetary policy. Among the most important real factors are shocks to the supply and demand for different components of the consumption basket. We use an estimated multi-sector New Keynesian model to decompose the behavior of U.S. inflation into contributions from sectoral (or "relative price") shocks, monetary policy shocks, and aggregate real shocks. The model is estimated by maximum likelihood with U.S. data for the post-1994 period in which inflation and the monetary policy regime appeared to be stable. In addition to providing a broad decomposition of inflation behavior, we enlist the model to help us understand the inflation shortfall from 2012 to 2019, and its surge in the aftermath of the pandemic.

JEL classification: E31, E52, E58
Key Words: Monetary policy, sectoral shocks, inflation shortfall, inflation surge, COVID-19.

1. Introduction

This paper quantifies the influence of real factors and monetary policy on U.S. inflation under the stable policy regime in place since 1995 and in two recent episodes, namely the shortfall of inflation from target in 2012-2019 and its surge in the aftermath of the pandemic. By real factors, we mean not just aggregate shocks, but the sectoral supply and demand shocks that drive relative price changes across consumption categories. Examples of such shocks are the earthquake in Japan in March 2011 that served as a negative supply shock for memory chips, and the COVID pandemic in March 2020 that served as a negative demand shock for in-person services. Following Reis and Watson (2010) we refer to these shocks as "relative price" shocks and provide model-based evidence that motivates this label: that sectoral shocks lead to large movements in the relative price of goods produced by the sector affected by the shock, and smaller responses in the relative price of other goods.[1] The analysis is based on an estimated multi-sector New Keynesian model with the 15 consumption categories that comprise the Personal Consumption Expenditures (PCE) price index and heterogeneity in price rigidity, in the volatility of sectoral productivity and demand shocks, and in the rate of productivity growth across sectors.

The view we take here is that although monetary policy could in theory offset real factors and perfectly stabilize inflation, this does not happen in practice and, thus, we observe instead a policy that results in equilibrium fluctuations in inflation. This motivates our objective of quantifying the relative contributions of monetary policy and relative price shocks to the behavior of U.S. inflation. The issue is important because central banks are accountable to the public and called to explain sustained deviations from stated price-stability policies (like inflation targets). This explanation, however, requires an economic model that can causally establish to what extent these deviations arise from shocks outside the control of the central or from monetary policy itself. This is the task that we undertake in this paper.

Analysis like ours immediately confronts the issue of monetary policy regimes. At one extreme, if there is a stable underlying monetary policy regime, then the tools of rational expectations and local approximation of dynamic stochastic general equilibrium (DSGE) models may be appropriate. At another extreme, clearly identified breaks in regime can be the source of facts against which

[1] This is so even in the presence of complementarities in consumption. In order to focus on the mechanism that we want to highlight here, we abstract from the complementarities in production considered by the literature on production networks. Balke and Wynne (2000, p. 286) report that input-output effects on their own do not appear to deliver significant interactions between inflation and the characteristics of the cross-section distribution of price changes. This may be partly due to the fact that at low levels of disaggregation, the Input-Output (I-O) Table features large entries along the main diagonal. In the polar case where the I-O Table is diagonal and there are no input-output interactions, the amplification of monetary policy shocks would arise solely from the presence of intermediate goods in the production function as in Basu (1995). We leave these issues for future research.

theories are evaluated, but the researcher must decide how to model information sets of private agents and the policy-maker. The fundamental assumption of this paper is that from January 1995 to December 2019 the United States was in a stable, well-understood monetary policy regime and that it is appropriate to use a locally approximated model with rational expectations to study that period. Under the assumption that the economy has remained in the pre-pandemic rational expectations equilibrium, we perform an out-of-sample analysis to quantify the contribution of relative price shocks and monetary policy to the drop in inflation in 2020 and its subsequent surge.

This paper makes three contributions to the literature. The first contribution involves basic analysis of inflation and relative price shocks. We construct and estimate a model with 15 consumption categories that addresses the empirical observations that the mean and standard deviation of sectoral price changes are different across categories. The model accounts for the first observation by allowing different rates of productivity growth across categories as in Balassa (1964) and Samuelson (1964), and it accounts for the second observation by postulating different volatility in sectoral shocks and price adjustment costs across categories. We estimate the model on monthly data from 1995-2019 by maximum likelihood and decompose inflation into the contribution of monetary policy shocks and shocks to demand and productivity in each of the consumption categories. Over the sample, inflation was low and stable, but nonetheless exhibited substantial month-to-month volatility. One way we evaluate the model fit is through its ability to match the historical relationship between the monthly inflation rate and the distribution of relative price changes. As discussed in our work with A. Hornstein (Hornstein et al., 2023), from 1995 to 2019 there was a tight negative relationship between the monthly inflation rate and the share of consumption expenditures exhibiting relative price increases. Our model reproduces and explains that relationship.

The second contribution is to decompose the shortfall of inflation from target in the 2012-2019 period. According to this decomposition, which uses the smoothed estimates of the structural shocks of the model, the largest contributors to the cumulative shortfall of the price level from the 2% trend implied by the Fed's target were the aggregate productivity shock (initially) and shocks to gasoline and energy goods and to health care. Note that we are intentionally describing causality: absent a model, when one analyzes inflation and category price changes, it is only possible to describe the extent to which the price change in a particular category accounts for inflation. Instead, the model allows us to provide estimates of the extent to which particular shocks caused the inflation shortfall. In particular, we conclude that about one-third of the inflation shortfall in 2012-2019 is attributable to monetary policy. Hence, U.S. monetary policy was mildly restrictive compared with the stance that would have been consistent with the inflation target of 2%.[2]

[2] A leading theoretical explanation for the inflation shortfall is that it resulted from the interaction between the

The third contribution is an out-of-sample analysis of the high inflation episode that began in March 2021 during the pandemic. As with the inflation shortfall, we decompose inflation into contributions of the sectoral shocks and monetary policy. Here, however, the smoothed estimates of the model's shocks use out-of-sample data, as our estimation sample ends in December 2019. In conducting local analysis around the model's (trending) steady state, we assume that the same policy rule remains in place during this high inflation episode. Under this assumption, we find that monetary policy was roughly consistent with the 2% target during the pandemic and accounts for only 1/4 of the inflation surge. Instead, most of the surge was driven by relative price shocks—both productivity and, especially, demand—to motor vehicles, gasoline, and housing.

The paper proceeds as follows. Section 2 contains a review that places our work in the literature and highlights our contribution. Section 3 describes the model and its balanced growth path. Section 4 describes the empirical analysis and reports parameter estimates. Section 5 presents the basic analysis of inflation and relative price shocks. Sections 6 and 7 cover the inflation shortfall and its post-pandemic surge, respectively. Section 8 concludes. An appendix shows our filtering strategy to decompose the contribution of each shock starting from the state-space representation of the model solution and taking into account the indirect effect of the shocks via the endogenous state variables.

2. Literature Review

We find it helpful to split our discussion of the vast literature on relative prices and inflation into two parts: first, research that pre-dates the COVID pandemic, and second, research specifically concerned with inflation during the pandemic and its subsequent surge.

2.1 Pre-Pandemic

There is a large and varied literature on relative prices and inflation that pre-dates the pandemic. One branch of the literature focuses on the role of oil shocks in driving short-run inflation fluctuations (see, for example, Kilian and Zhou, 2021, and the references therein). Our paper embodies a generalization of that mechanism: we find that oil shocks are the most volatile relative price shocks, but that in any given period other categories experience unusually large shocks that ac-

lower bound on nominal interest rates and the Fed's implicit policy rule (see, for example, Bianchi et al., 2021). Our current results cannot speak directly to that view because we do not explicitly impose a lower bound on the interest rate. However, we treat the interest rate as a latent variable during the estimation procedure in the spirit of the econometric model of the shadow federal funds rate in Wu and Xia (2016). Thus, the most constructive way to interpret the 1/3 contribution from monetary policy shocks to the shortfall is as a lower bound for the effects of the zero bound during this period.

count for sizable movements in inflation. Another branch of the literature studies causality in the opposite direction, that is, from inflation to the variability of relative prices. These papers are concerned mainly with periods when inflation was not stable—in particular papers from the 1970s and 1980s, with Parks (1978) being a key reference. In principle, our model can have inflation (i.e., policy) affect relative price variability but in practice that channel is weak, as one would expect in a stable policy regime like one we consider. While our analysis is conducted in the context of an estimated DSGE model, several papers analyze the empirical relationship between inflation and the distribution of price changes from a statistical perspective. A leading example of this research is Reis and Watson (2010), who employ a factor model and conclude that most inflation volatility is associated with relative-price movements. As we will see, our structural model leads us to the same conclusion.

The papers closest to ours are Ball and Mankiw (1995), Balke and Wynne (2000), and Smets et al. (2019). Like us, they each bring some theory to bear on the relationship between relative prices and inflation. Ball and Mankiw (1995) note that there is an empirical relationship between the level of inflation and measures of asymmetry in the distribution of relative price changes. They proposed an explanation based on a menu cost model: with fixed costs of price adjustment, inflation tends to move with the price change of sectors hit by the largest shocks to their desired price while prices do not change in sectors hit by small shocks to their desired price. In our model, Rotemberg costs mean that any firm hit by a shock will adjust its price. In equilibrium, the interaction of policy and shocks delivers a relationship between inflation and the distribution of actual relative prices consistent with the data.

Balke and Wynne (2000) argue that the pattern identified by Ball and Mankiw can be explained without relying on sticky prices. These authors calibrate a multi-sector RBC model where monetary policy is characterized by a constant money growth rule. Our paper extends Balke and Wynne by estimating a richer model where monetary policy follows a standard feedback rule for the nominal interest rate, and in which the degree of price stickiness is allowed to vary across consumption categories. Like Smets et al. (2019), we estimate a DSGE model and use the Kalman filter to decompose the behavior of inflation into aggregate and sectoral shocks. They study network interactions absent from our model and estimate over a longer sample in which inflation was not stable.[3] In comparison to these papers, our analysis concentrates on the period from 1995 to 2019 when the monetary policy regime was stable, so that the conditions for estimating a rational expectations model that is approximated around a steady state are more likely to be satisfied.

[3] See also Pasten et al (2024), who discuss the importance of sectoral shocks for inflation in a DSGE model with input-output structure using a calibrated model.

Our paper also relates to the literature that studies how the Phillips curve can appear to flatten when policy is conducted optimally so as to stabilize inflation. McLeay and Tenreyro (2020) is a leading example of that research. While we abstract from optimal policy, in practice the Federal Reserve did stabilize inflation from 1995-2019 and this is embodied in our estimated model. We emphasize that the remaining small fluctuations in inflation are associated with variation in relative prices across categories, as opposed to Phillips curve channels. Borio et al. (2021) also emphasize that in a stable monetary policy regime, sector-specific factors can play a major role in driving inflation.

2.2 Inflation During the Pandemic and Its Aftermath

Our paper provides a model-based accounting for the behavior of U.S. inflation in which inflation is determined by the interaction of monetary policy with a variety of shocks, most notably shocks to supply and demand for different categories of consumption. Although our work was begun before the pandemic, we do apply it to study inflation during and after the pandemic. There has been an explosion of research that attempts something similar, and in this section we list many of those recent papers and explain what sets our work apart. The key general points are as follows. First, we are focused on how inflation is determined through the interaction between monetary policy, other aggregate shocks, and shocks that fundamentally affect relative prices and we abstract from how sector-specific demand and supply shocks propagate through the economy. Second, we estimate our model on data from the period January 1995 to January 2020 when policy was stable. Finally, our model is fully dynamic and estimation includes the monetary policy rule and the processes driving sectoral supply and demand shocks to 15 consumption categories that comprise the PCE.

Rubbo (2022) calibrates a model richer than ours, with a larger number of sectors and a network structure. By estimating our model under full information we are able to overcome an important issue raised by Rubbo (p. 38), namely that "it is difficult to distinguish the components of aggregate inflation driven by the output gap vs relative demand and supply shocks, because we do not observe the aggregate output gap nor the relative price wedges." In addition, Rubbo models monetary policy as a money supply rule that makes nominal income exogenous, while we estimate instead an interest rate feedback rule. di Giovanni et al. (2023) analyze a multi-country version of the model in Baqaee and Farhi (2022), which also features a network structure. This model is essentially static, while ours is dynamic and allows us to study inflation as resulting from the interaction between monetary policy and sectoral shocks to supply and demand.

Similar to our paper, Gagliardone and Gertler (2023) provide decompositions of inflation into the contributions of sectoral and aggregate shocks in an estimated DSGE model. However, their

analysis is limited to two sectors, oil and non-oil, but the pandemic experience showed that inflation can be associated with large changes in relative prices other than food and energy. Ferrante et al. (2023) analyze the pandemic as a shock that reallocates demand from services to goods using a 66-sector model with input-output structure. Our model has fewer sectors and deliberately abstracts from an input-output structure to focus on alternative mechanisms. While our estimation does not cleanly describe the pandemic as a reallocation shock, we provide additional analysis of how such a shock would work in our model.

Gao and Nicolini (2023) examine the inflation surge through the lense of the Quantity Theory and argue that it primarily reflects shocks outside the control of the monetary authority. Finally, Comin et al. (2023) study an open-economy model with supply-chain constraints and argue that this channel was an important determinant of inflation during the pandemic. Working with a closed-economy model, we abstract from interactions between local and domestic producers, but can shed light on the relative contribution of monetary policy and sectoral shocks to inflation during the pandemic and to is subsequent surge.

3. The Model

The economy consists of an infinitely-lived representative household, continua of firms in a finite number of sectors, and a monetary authority. Firms are monopolistic-competitors that each produce a differentiated good using labor as the sole input of production.

3.1 Households

The household maximizes

$$E_\tau \sum_{t=\tau}^{\infty} \beta^{t-\tau} e^{\eta_t} \left(\ln\left(C_t\right) + \psi \frac{\left(1-N_t\right)^{1-\chi}}{1-\chi} \right), \tag{1}$$

where E_τ denotes the conditional expectation as of time τ, $\beta \in (0,1)$ is the discount factor, η_t is a preference shock, C_t is consumption, N_t is hours worked, and ψ and χ are positive preference parameters. The time endowment is normalized to be one. The preference shock follows the process,

$$\eta_t = \varrho \eta_{t-1} + \varsigma_t, \tag{2}$$

where $\varrho \in (-1,1)$ is a parameter and ς_t is an independent and identically distributed (i.i.d.) innovation drawn from a normal distribution with mean zero and variance σ_ς^2.

Consumption is an aggregate of goods produced in different sectors $s = 1, 2, \ldots, S$,

$$C_t = \prod_{s=1}^{S} \left(\xi^s\right)^{-\xi^s} \left(c_{s,t} - u_{s,t}\right)^{\xi^s}, \tag{3}$$

where $\xi^s \in (0,1)$, $\sum_{s=1}^{S} \xi^s = 1$, $c_{s,t}$ is consumption of goods produced in sector s, and $u_{s,t}$ is a sector-specific demand shock. The demand shock follows the process,

$$u_{s,t} = \varrho_s u_{s,t-1} + \zeta_{s,t}, \tag{4}$$

where $\varrho_s \in (-1,1)$ is a parameter and $\zeta_{s,t}$ is an i.i.d. innovation drawn from a normal distribution with mean zero and variance $\sigma^2_{\zeta,s}$. Within each sector, there is a continuum of monopolistically-competitive firms that each produce a differentiated good. The household's preferences for these goods are represented by the CES aggregator

$$c_{s,t} = \left(\int c_{i,s,t}^{(\theta-1)/\theta} \right)^{\theta/(\theta-1)}, \tag{5}$$

where $c_{i,s,t}$ is consumption of the good produced by firm i in sector s and $\theta > 1$ is the elasticity of substitution between goods produced in the same sector.

In every period, the household faces the budget constraint

$$P_t C_t + B_t \leq P_t w_t N_t + R_{t-1} B_{t-1} + D_t, \tag{6}$$

where P_t is the aggregate price level, B_t is nominal bonds, w_t is the real wage, R_t is the gross nominal interest rate, and D_t are profits from firms, which are transferred to the household in the form of dividends. The price index is

$$P_t = \prod_{s=1}^{S} \left(P_{s,t} \right)^{\xi_s}. \tag{7}$$

The solution to the household's maximization problem shows that the optimal labor supply satisfies

$$\frac{\psi \left(1 - N_t\right)^{-\chi}}{1/C_t} = w_t, \tag{8}$$

meaning that the marginal rate of substitution between leisure and consumption equals the real wage; the optimal consumption of good i produced in sector s is

$$c_{i,s,t} = \xi_s \left(\frac{P_{i,s,t}}{P_{s,t}} \right)^{-\theta} \left(\frac{P_{s,t}}{P_t} \right)^{-1} C_t + u_{s,t}, \tag{9}$$

where

$$P_{s,t} = \left(\int P_{i,s,t}^{1-\theta} di \right)^{1/(1-\theta)} \tag{10}$$

is a sector-specific price index; and the optimal (total) consumption satisfies the intertemporal Euler equation

$$\frac{e^{\eta_t}}{P_t C_t} = \beta R_t E_t \left(\frac{e^{\eta_{t+1}}}{P_{t+1} C_{t+1}} \right). \tag{11}$$

3.2 Firms

Firm $i \in (0,1)$ in sector s produces output using the technology

$$y_{i,s,t} = e^{a_t} e^{z_{s,t}} \left(n_{i,s,t}\right)^{\alpha}, \tag{12}$$

where $y_{i,s,t}$ is output, e^{a_t} and $e^{z_{s,t}}$ are, respectively, the aggregate and sectoral levels of productivity, $n_{i,s,t}$ is labor input, and $\alpha \in (0,1)$ is a parameter. The assumption $\alpha \in (0,1)$ implies that the firm faces decreasing returns to labor.[4] Labor is completely mobile across firms and sectors.[5] Sectoral productivity follows the process,

$$z_{s,t} = (1-\rho_s)\mu_s + z_{s,t-1} + \rho_s(z_{s,t-1} - z_{s,t-2}) + \epsilon_{s,t}, \tag{13}$$

where μ_s is a drift, $\rho_s \in (-1,1)$ is a parameter, and $\epsilon_{s,t}$ is an i.i.d. innovation drawn from a normal distribution with mean zero and variance $\sigma^2_{z,s}$. We allow for different drifts across sectors so that our model can account for the trends in relative prices observed in the data. Aggregate productivity follows the process,

$$a_t = (1-\rho)\mu + a_{t-1} + \rho(a_{t-1} - a_{t-2}) + \varepsilon_t, \tag{14}$$

where μ is a drift, $\rho \in (-1,1)$ is a parameter, and ε_t is an i.i.d. innovation drawn from a normal distribution with mean zero and variance σ^2_a. Without loss of generality, we normalize $\mu = 0$. Results would be unchanged if we were to allow an non-zero stochastic trend in aggregate productivity—for instance, equal to the growth rate of aggregate output and with sectoral trends adjusted accordingly—because what matters in this model are relative productivity trends rather than absolute ones. The maintained assumption in this paper is that the trends in relative prices observed in the data are driven by productivity differentials across consumption categories.

Each firm must incur a cost when it changes its nominal price. The cost is convex in the size of the adjustment and is specified in terms of units of labor. The per-unit cost, $\Phi_{i,s,t}$, for firm i in sector s in period t is

$$\Phi_{i,s,t} = \Phi\left(P_{i,s,t}, P_{i,s,t-1}\right) = \frac{\phi_s}{2}\left(\frac{P_{i,s,t}}{\pi_s P_{i,s,t-1}} - 1\right)^2 n_{i,s,t}, \tag{15}$$

[4] Decreasing returns to labor are important for our analysis because it allows demand shocks to affect relative prices. Under constant returns to labor and in the polar case where prices are flexible, relative prices are equal to the inverse of relative sectoral productivity and invariant to demand shocks.

[5] In order to keep the model tractable, we abstract from potentially important frictions in the labor market and leave them for future research. Regarding the recent inflation surge, Bernanke and Blanchard (2023) conclude that labor market tightness made a modest contribution to inflation (at least initially) and that most of the early increase in inflation came from the goods market. Research that examines the role of the labor market in the inflation surge includes, among others, Ball et al. (2022) and Amiti et al. (2023).

where $\phi_s \geq 0$ and π_s is the steady-state sectoral rate of price change. There is complete indexation to the sectoral rate of price changes.[6] The firm chooses output, labor input, and the price of its good to maximize profits, where costs comprise labor costs and adjustment costs. The maximization is subject to the demand function (9) and the technology (12). The solution to this problem delivers the following optimality condition for firm i in sector s:

$$
\begin{aligned}
(\theta-1)\left(\frac{P_{i,s,t}}{P_{s,t}}\right)^{-\theta}\frac{y_{s,t}P_{s,t}}{w_tP_t} &= \frac{\theta P_{s,t}}{\alpha P_{i,s,t}}\left(\left(\frac{P_{i,s,t}}{P_{s,t}}\right)^{-\theta}\frac{y_{s,t}}{e^{a_t}e^{z_{s,t}}}\right)^{1/\alpha} \\
&+\frac{\theta P_{s,t}}{\alpha P_{i,s,t}}\frac{\phi_s}{2}\left(\frac{P_{i,s,t}}{\pi_s P_{i,s,t-1}}-1\right)^2\left(\left(\frac{P_{i,s,t}}{P_{s,t}}\right)^{-\theta}\frac{y_{s,t}}{e^{a_t}e^{z_{s,t}}}\right)^{1/\alpha} \\
&-\phi_s\left(\frac{P_{i,s,t}}{\pi_s P_{i,s,t-1}}-1\right)\left(\left(\frac{P_{i,s,t}}{P_{s,t}}\right)^{-\theta}\frac{y_{s,t}}{e^{a_t}e^{z_{s,t}}}\right)^{1/\alpha}\frac{P_{s,t}}{\pi_s P_{i,s,t-1}} \\
&+E_t\left(\frac{w_{t+1}}{w_tR_t}\frac{P_{s,t}P_{t+1}}{P_{i,s,t}P_t}\phi_s\left(\frac{P_{i,s,t+1}}{\pi_s P_{i,s,t}}-1\right)\left(\left(\frac{P_{i,s,t+1}}{P_{s,t+1}}\right)^{-\theta}\frac{y_{s,t+1}}{e^{a_{t+1}}e^{z_{s,t+1}}}\right)^{1/\alpha}\frac{P_{i,s,t+1}}{\pi_s P_{i,s,t}}\right).
\end{aligned}
\tag{16}
$$

This equation relates the optimal price selected by firm i to its marginal cost, including that associated with current and future expected price adjustments.

3.3 Monetary Policy

The monetary authority sets the nominal interest rate following the rule,

$$
R_t = \delta R_{t-1} + (1-\delta)(1/\beta)\exp\left(\pi + \gamma_y + \lambda_\pi\left(\pi_t - \pi\right) + \lambda_y\left(\ln(Y_t) - \ln(Y)\right)\right) + v_t, \tag{17}
$$

where $\delta \in (-1,1)$, λ_π, and λ_y are parameters representing responsiveness to the lagged interest rate, inflation, and output, respectively, π_t is the gross inflation rate ($= P_t/P_{t-1}$), γ_y is the growth rate of output (see below), π is a policy parameter denoting the inflation target, Y_t is aggregate output, Y is output in the balanced-growth steady state, and v_t is a disturbance that represents movements in the interest rate beyond the control of the central bank. This disturbance is assumed to be i.i.d. and drawn from a normal distribution with mean zero and variance σ_v^2.

3.4 Equilibrium and Balanced Growth Path

The equilibrium of the model is symmetric within sectors but asymmetric across sectors. That is, in equilibrium, all firms within a sector are identical and make exactly the same choices (labor

[6] In the working paper version of this article (Ruge-Murcia and Wolman, 2022), we assumed indexation to a convex combination of the sectoral rate of price changes and the aggregate inflation rate. However, we found that the coefficients of this combination were poorly identified by the dynamics of sectoral inflation. The specification that we adopt here has the advantage that adjustment costs are zero in the deterministic steady state.

input, price, and output), but firms in different sectors make different choices. In particular, firms in different sectors choose different prices and, hence, rates of price change will differ across sectors. In a symmetric equilibrium we can simplify the optimality conditions by dropping the i subscripts, and we impose market clearing in the different markets. Since we will approximate the model solution around a steady state with long-term growth, it is also helpful to derive some relationships between the steady state growth rates of different variables.

3.4.1 Sectoral Phillips Curve

The fact that firms in the same sector are identical in equilibrium means that the price charged by each firm is equal to the sectoral price index,

$$P_{i,s,t} = P_{s,t},\ s = 1, 2, \ldots, S.$$

The firm's optimality condition can then be written as the sectoral Phillips curve,

$$\begin{aligned}(\theta - 1)\frac{y_{s,t}P_{s,t}}{w_t P_t} &= \frac{\theta}{\alpha}\left(\frac{y_{s,t}}{e^{a_t}e^{z_{s,t}}}\right)^{1/\alpha} + \frac{\theta}{\alpha}\frac{\phi_s}{2}\left(\frac{\pi_{s,t}}{\pi_s} - 1\right)^2\left(\frac{y_{s,t}}{e^{a_t}e^{z_{s,t}}}\right)^{1/\alpha} \\ -\phi_s\left(\frac{\pi_{s,t}}{\pi_s} - 1\right)\left(\frac{y_{s,t}}{e^{a_t}e^{z_{s,t}}}\right)^{1/\alpha}\frac{\pi_{s,t}}{\pi_s} &+ E_t\left(\frac{w_{t+1}\pi_{t+1}}{w_t R_t}\phi_s\left(\frac{\pi_{s,t}}{\pi_s} - 1\right)\left(\frac{y_{s,t+1}}{e^{a_{t+1}}e^{z_{s,t+1}}}\right)^{1/\alpha}\frac{\pi_{s,t}}{\pi_s}\right),\end{aligned} \tag{18}$$

where $\pi_{s,t} = P_{s,t}/P_{s,t-1}$. As in previous literature that derives sectoral Phillips curves in multi-sector economies (e.g., Imbs et al., 2011, and Rubbo, 2022), the slope of the linearized Phillips curve is heterogenous across sectors, in our case as a result of heterogeneity in price rigidity.

3.4.2 Market Clearing

There is a goods market clearing condition in each sector

$$y_{s,t} = c_{s,t},$$

for $s = 1, 2, \ldots, S$, and a labor market clearing condition for the economy as a whole

$$N_t = \sum_{s=1}^{S} n_{s,t} + F_t,$$

where F_t is total adjustment costs

$$F_t = \sum_{s=1}^{S}\left(\frac{\phi_s}{2}\left(\frac{\pi_{s,t}}{\pi_s} - 1\right)^2 n_{s,t}\right).$$

3.4.3 Steady-state Growth Rates

The model has an exogenous growth rate for the overall price index in the balanced growth path. That growth rate, π, is determined by the inflation target in the policy rule. The model also has S exogenous trend growth rates for sectoral productivity, μ_s. Each sector's output growth rate is equal to its productivity growth rate. Productivity growth rates determine the growth rates of output and the real wage. Then, the inflation target, along with the productivity growth rates, determine the growth rates of sectoral prices as follows:

$$\gamma_y = \gamma_w = \sum_{s=1}^{S} \xi_s \mu_s, \tag{19}$$

$$\pi_s = \pi + \gamma_w - \mu_s = \pi + \sum_{j=1}^{S} \xi_j \left(\mu_j - \mu_s\right). \tag{20}$$

The trend growth (or decline) in sectoral *relative* prices is determined entirely by a real factor, namely sectoral relative productivity growth,

$$\pi_s - \pi = -\mu_s + \sum_{j=1}^{S} \xi_j \mu_j.$$

In the international trade literature, this mechanism underpins the celebrated Balassa-Samuelson effect whereby different rates of productivity growth in the tradeable good sector compared with the non-tradeable good sector can induce a trend in the real exchange rate (see, e.g., Balassa, 1964). We stress that while sectoral relative prices can move around temporarily because of monetary policy shocks or the interaction between real shocks and the policy rule, the trend in relative prices is invariant to monetary policy and to parameters representing price stickiness.

The model is solved using a first-order perturbation with the rational-expectation solution of the linearized system found using the approach in Klein (2000).

4. Empirical Analysis

In this section, we describe the data used for estimation and the estimation method, and we discuss the parameter estimates.

4.1 Data

The data used to estimate the model are monthly observations of the rates of price change and real per-capita consumption growth for fifteen consumption expenditure categories of the U.S. economy

from 1995M1 to 2020M1. The use of both price and quantity data help us identify the processes of demeand and productivity (i.e., supply) shocks, in addition to the other parameters of the model. The sample starts around the time that the Federal Reserve Board settled on implicitly targeting an inflation rate of 2% per year (see the transcripts of the meeting of the Federal Open Market Committee on January 31). The inflation target was officially adopted in January 2012 and applies to the personal consumption expenditures (PCE) price index.

The fifteen categories comprise all of the PCE except for the final consumption expenditures of nonprofit institutions serving households, which we exclude from our analysis. The sectors are motor vehicles and parts, furnishings and household durables, recreational goods, other durable goods, food consumed at home, clothing and footwear, gasoline and other energy goods, other nondurable goods, housing and utilities, health care, transportation services, recreation services, food services and accommodations, financial services and insurance, and other services. The raw data used to construct the sectoral price changes are seasonally adjusted price indices available from the website of the Bureau of Economic Analysis (www.bea.gov).

The raw data used to construct the sectoral consumption growth rates are monthly nominal expenditures produced by the BEA. The consumption and price series correspond exactly to the same categories. The consumption series are converted into real per-capita terms by dividing by the seasonally-adjusted PCE price index and by the mid-month U.S. population estimate produced by the BEA. The latter series was obtained from the website of the Federal Reserve Bank of St. Louis. To be consistent with the model solution, which describes the dynamics of the variables in deviation from their steady state values, all data series are demeaned prior to the structural estimation of the model.

4.2 ML Estimation

The model is estimated by the method of maximum likelihood (ML) using the Kalman filter to evaluate the likelihood function. The state equation of the state-space representation of the model solution is the joint process of exogenous and predetermined variables,

$$X_{t+1} = HX_t + \vartheta_{t+1},$$

where X_t and ϑ_t are $(4S + 5) \times 1$ vectors with S being the number of sectors, and H is a $(4S + 5) \times (4S + 5)$ matrix with the parameters of the exogenous shock processes and the coefficient of the decision rules of the endogenous predetermined variables. The observation equation is

$$Q_t = GX_t,$$

where Q_t is a $2S \times 1$ vector and G is a $2S \times (4S+5)$ matrix whose elements are the coefficients of the decision rules of sectoral price changes and sectoral rates of consumption growth. The coefficients of the decision rules are nonlinear functions of the structural parameters. As it is well known, this estimation approach is equivalent to using a Bayesian estimation strategy with diffuse priors. Hansen and Sargent (2013, ch. 8) shows that the ML estimator obtained by applying the Kalman filter to the state-space representation of dynamic linear models is consistent and asymptotically efficient. Standard errors are estimated by the square root of the diagonal elements of $(T\mathcal{I})^{-1}$ where T is the sample size and $\mathcal{I}$ is the information matrix, which is computed using the outer product of the scores at the maximum.

A difficulty that we face in estimating this model is that the steady state has to be computed numerically in every iteration of the algorithm that maximizes the likelihood function. Given the relatively large size of our model, this computation is time-consuming. In order to address this challenge, we first fix the parameters that determine the steady state and, with these parameters set, we estimate the parameters that determine the dynamics of the model by ML. The parameters that determine the steady state are fixed as follows. The weight of leisure in the utility function (ψ) is set to 1.8, such that households work 1/3 of the time in steady state. The preference parameter χ is fixed to 1 so that utility is linear on leisure as in the indivisible labor model in Hansen (1985). The parameter that determines the elasticity of substitution between goods from the same sector (θ) is fixed to 10. This value is standard in the literature and implies a mark-up of approximately 10%. The elasticity parameter in the production function (α) is fixed to 0.75, but results are robust using other plausible values. The discount rate (β) is fixed to 0.998.

In preliminary work, we estimated separate autoregressive coefficients for each sectoral demand and supply shock. However, estimates of the autoregressive coefficient of the sectoral demand shocks, on the one hand, and of the sectoral supply shocks, on the other, were quantitatively very similar. These results indicate that the heterogeneity in sectoral shocks is primarily driven by heterogeneity in the standard deviation of their innovations. Imposing the restrictions $\varrho_s = \varrho$ and $\rho_s = \rho$ for all s is, thus, in rough agreement with the data and reduces the number of parameters to be estimated from 81 to 53 with substantial gain in computational and statistical efficiencies.

The consumption weights are computed using the consumption expenditure shares in each sector. Recall that the optimal consumption of good i produced in sector s is

$$c_{i,s,t} = \xi_s \left(\frac{P_{i,s,t}}{P_{s,t}} \right)^{-\theta} \left(\frac{P_{s,t}}{P_t} \right)^{-1} C_t + u_{s,t}.$$

Using the fact that the equilibrium is symmetric within sectors, which implies $P_{i,s,t} = P_{s,t}$, setting

$u_{s,t}$ equal to is unconditional mean (which is zero), and solving for ξ_s delivers

$$\xi_s = \frac{P_{s,t}c_{s,t}}{P_t C_t},$$

where $P_{s,t}c_{s,t}$ are expenditures in sector s and $P_t C_t$ are total consumption expenditures. Estimates of ξ_s for each sector are reported in Column 1 of Table 1.

Finally, the model suggests a natural strategy to estimate the trends in sectoral productivity based on the result that sectoral price changes in steady state are

$$\pi_s = \pi + \gamma_c - \mu_s, \tag{21}$$

for $s = 1, 2 \ldots, S$. Solving for μ_s, so that $\mu_s = \pi + \gamma_c - \pi_s$, and using the fact that the model implies that the steady state values of aggregate inflation, aggregate consumption growth, and sectoral price changes are equal to their respective unconditional means, delivers estimates of μ_s for each sector. These estimates are reported in Column 2 of Table 1. Our estimates suggest that recreational goods feature the largest rate of productivity growth in the U.S. economy, which accounts for the persistent decrease of the nominal price of goods in this consumption category at the rate of 0.5% per month, or about 6% per year.[7]

4.3 Parameter Estimates

Maximum likelihood estimates of sector-specific parameters—that is, price rigidity and the standard deviation of innovations of sectoral productivity and demand shocks—are reported in Table 2. Remaining ML estimates, including the parameters of the Taylor rule, are reported in Table 3.

Note in Table 2 that there is substantial heterogeneity in price rigidity across sectors and the null hypothesis that rigidity is the same in all sectors is rejected by the data (see the p-value of the Wald test reported in the last row of Table 2). Heterogeneity in price rigidity across product categories has been documented by previous literature using highly disaggregated components of the consumer price index (CPI) (see, among others, Bils and Klenow, 2004, Klenow and Kryvtsov, 2008, and Nakamura and Steinsson, 2008) and estimated multi-sector dynamic equilibrium models (see, e.g., Bouakez et al., 2014). In line with that literature, we find that price adjustment costs are generally higher in services than in other sectors. One exception is financial services and insurance for which the null hypothesis that the cost parameter is zero (i.e., $\phi = 0$), and thus prices are flexible, cannot be rejected at the 5% level. The prices of most categories of durables and nondurable goods are also rigid in the sense that the hypothesis $\phi = 0$ can be rejected at standard levels (e.g., food

[7] Note that in line with Balassa (1964) and Samuelson (1964), the sectors with the highest productivity growth produce tradeable goods, while the sectors with the lowest productivity growth produce nontradeable goods (services).

at home and recreational goods). There are, however, some categories like gasoline and energy goods for which the hypothesis cannot be rejected at the 5% level. Quantitatively, the largest price rigidity parameters are those of motor vehicles and parts, and housing and utilities. In terms of the expenditure shares, 84% of consumption by U.S. households may be considered to have rigid prices.

The autoregressive coefficient of the first-difference of sectoral productivity shocks is statistically significant but quantitatively small: -0.244 (0.027), where the figure in parenthesis is the standard error. This suggests that sectoral productivity is well approximated by a random walk with drift, with different drift for different sectors. There is large heterogeneity in the standard deviation of productivity innovations and the hypothesis that they are the same in all sectors is rejected by the data. The largest standard deviation is that of gasoline and energy goods, followed by motor vehicles and parts, both of which are one order of magnitude larger than that of other sectors. The standard deviation of aggregate productivity innovations in Table 3 is moderately large and comparable in magnitude to that of several sectoral productivity shocks.

The autoregressive coefficient of the sectoral demand shock is 0.992 (0.003). Table 2 shows that there is large heterogeneity in the standard deviation of demand innovations and the hypothesis that they are the same in all sectors is rejected by the data. The largest standard deviations are those of gasoline and energy goods, and motor vehicles and parts, which are again one order of magnitude larger than that of other sectors. Comparing Columns 3 and 5 in Table 2 shows that the innovations to productivity shocks are one order of magnitude larger than that of innovations to demand shocks in all sectors.

The finding that the standard deviation of both supply and demand shocks to gasoline and energy goods, and to motor vehicles and parts are large explains why the observed frequency of price adjustments for these goods is high despite the fact that their price rigidity parameter is large and statistically significant. For example, Bils and Klenow (2004, p. 983) report that the estimated average monthly frequency of price changes for gasoline over 1995–1997 ranges between 76.2 and 78.9 depending on its grade. The frequency of price changes for new cars and new trucks, which are the largest components of the motor vehicles and parts category, are 39.1 and 37.7, respectively, and much higher than the frequency for the average good in their sample. This result is important for several reasons. First, it shows that the frequency of price adjustment is an imperfect indicator of the actual costs that firms face when adjusting prices: Price adjustment costs may be substantial but the large volatility of sectoral shocks may nevertheless induce firms to optimally adjust prices frequently. Second, this result shows that the heterogeneity in the frequency of price adjustments documented in earlier literature may be partly driven by heterogeneity in sector-specific shocks.

Finally, this result shows that, in addition to heterogeneity in price rigidity, it is important to include other forms of heterogeneity—in particular, heterogeneity in the volatility of idiosyncratic shocks—in multi-sector and network New Keynesian models.

In Table 3, the autoregressive coefficient of the preference shock is 0.818, but the standard deviation of its innovations is quantitatively small. Overall, the parameters of this shock are not precisely estimated.[8] Regarding the estimates of the monetary policy rule, note that the smoothing parameter is large (0.989), statistically significant, and in line with values reported elsewhere in the literature. The coefficients of inflation and output are positive and precisely estimated: 1.592 (0.602) and 0.658 (0.268), respectively. Although the standard deviation of the monetary policy shock is small, we will see below that monetary policy accounts for a non-negligible part of the variance of aggregate and sectoral inflation.

4.4 Model Fit

Table 4 reports the standard deviation and autocorrelation of aggregate inflation and sectoral price changes predicted by the model and compares them with U.S. data. In contrast to method of moments estimators (e.g., GMM or SMM), our ML estimation procedure does not explicitly target these moments.[9] The table shows that our model quantitatively captures the low autocorrelation of month-to-month inflation and sectoral price changes, and the volatility of all series, notably the large standard deviation of price changes in gasoline and other energy goods.

These results are reported in an alternative manner in Panel A of Figure 1, which graphically compares the moments predicted by the model (vertical axis) with those computed using the U.S. data (horizontal axis). The continuous line is the 45 degree line. If the model were to exactly match the moments of the data, all dots would lie on this line. The predicted volatility of price changes in gasoline and energy goods is somewhat lower than in the data (3.74 versus 4.99) but of similar magnitude. Overall, the panel shows that the moment predicted by the model are quantitatively in line with those of the data and the correlation between the two set of moments is high: 0.967.

Since the high correlation may be driven by the standard deviation of sectoral price changes in gasoline and in order to zoom into to the remaining moments, Panel B of Figure 1 performs the same comparison but excluding the standard deviation of sectoral price changes in gasoline. The

[8] In preliminary work, we estimated a version of the model without a preference shock and results are similar to those reported here.

[9] As it is well known, ML is the special case of GMM where the moment condition concerns the score vector (i.e., the gradient of the log-likelihood function with respect to the parameters). Thus, in the language of the calibration strategy frequently used in macroeconomics, the standard deviations and autocorrelations are "untargeted" moments. Notice that due to the condition (21) used to compute μ_s for each sector, our model matches perfectly the mean of sectoral price changes by construction.

panel shows that the autocorrelation of prices changes in motor vehicles predicted by the model (0.81) is higher than the value computed from the data (0.31). Conversely, the autocorrelation of prices changes in gasoline predicted by the model (-0.10) is lower than the value computed from the data (0.35). Counter-factual simulations indicate that these results are respectively driven by the relatively high (motor) and low (gasoline) estimates of the price adjustment cost parameter (see Table 2). However, in general, the plot in Panel B shows that the moments predicted by the model are quantitatively close to those of the data and the correlation between the two set of moments, after excluding the standard deviation of gasoline price changes, is still high: 0.726. In summary, we conclude that our model does a good job reproducing key moments of the U.S. inflation data.

Figure 2 plots the annual U.S. aggregate inflation rate measured by the PCE index (thick line) and the fit of the model obtained using the smoothed inference of the state vector computed using the Kalman filter (dash line). This figure shows that our estimated model tracks closely U.S. inflation. The R^2 of the fit is high and equal to 0.975. The R^2 of the fit based on the filtered inference (not reported) is basically the same up to the fourth decimal. These results underpin our analysis in Sections 5 and 6, where we decompose the model fit into the contributions of each exogenous shock.

5. Relative Price Shocks and Inflation over the Entire Sample

With parameter estimates in hand, we can now turn to the model's implications regarding the role of relative price shocks in driving inflation dynamics. We begin with impulse response analysis and variance decompositions. Then we focus on a summary statistic for the distribution of relative price changes that has not—to our knowledge—previously been examined in the literature.

5.1 Impulse Responses

Figure 3 reports the responses of relative prices ($P_{s,t}/P_t$) to a negative productivity shock in each sector. For example, Panel A reports the response of the relative price of motor vehicles (thick line) and other relative prices (thin lines) to a negative productivity shock in the motor vehicles sector. The size of the shock is one standard deviation of the productivity innovation, $\sigma_{z,s}$ (see (13)). In all panels, the productivity shock leads initially to a large increase in the relative price of the good produced in that sector. Because the shock is negatively—but mildly—autocorrelated, this increase is followed by a decrease and a quick convergence to the steady-state. In the case of motor vehicles (Panel A), the convergence is slower than in other sectors due the relatively high estimate of the price adjustment cost parameter. Fluctuations in the relative price of the good produced in the sector that receives the shock are one or more orders of magnitude larger than the

fluctuations in the relative price of goods produced by the other 14 sectors.[10] These 14 impulse responses are similar and sometimes appear as a single black line in Figure 3.

Figure 4 reports the responses of relative prices ($P_{s,t}/P_t$) to a negative demand shock in each sector with the size of the shock equal to one standard deviation of the demand innovation, $\sigma_{\zeta,s}$ (see (4)). In all panels, the demand shock leads to a large and persistent decrease in the relative price of the good produced in that sector (thick dashed line). This decrease is one or more orders of magnitude larger than the increase in the relative price of goods produced by the other 14 sectors (thin lines). Again, these 14 impulse responses are similar and sometimes appear as a single black line in Figure 4. The results in Figures 3 and 4 show that sectoral productivity and demand shocks yield a large response in the relative price of its own good and a only mild response in other relative prices motivates our interpretation of sectoral shocks as relative price shocks.

Figure 5 reports the response of inflation to aggregate and sectoral shocks. The horizontal axis is months, and the vertical axis is the inflation deviation from in steady state value, expressed in percentage points at an annual rate. Panel B reports the inflation response to a monetary policy shock that reduces the nominal interest by σ_ν. Panel C reports the inflation response to a negative preference shock of size σ_ζ. The other panels report the inflation response to negative productivity (thick blue line) and demand (thin red line) shocks with size equal to one standard deviation of their respective innovation. Note that the scale of the vertical axis is different across panels. This figure shows that different shock sizes across sectors and, to some extent, different price stickiness and size across sectors, imply heterogeneity in the effects of relative price shocks on inflation. Quantitatively, the largest effects are due to shocks to aggregate productivity (Panel A), monetary policy (Panel B), motor vehicles (Panel D), gasoline (Panel J), finance and insurance (Panel P), housing and utilities (Panel L), and health (Panel M).

5.2 Accounting for the Variance of Inflation

This section reports the variance decomposition for the inflation rate at different horizons. (Recall that this is the proportion of the mean squared error of the forecast of inflation at different horizons that is accounted for by each of the shocks.) Results for horizons are plotted in Figure 6 with the horizontal axis representing months and the vertical axis representing percentages. Panel A in Figure 6 shows that the aggregate productivity shock accounts for substantial proportion of the variance of the inflation forecast error at all horizons: upwards from 17% at all horizons. Panel B shows that monetary policy accounts for around 11.8% of the inflation forecast error at the

[10] Recall that the aggregate price index, P_t, is a geometric average of sectoral prices (see eq. (7)) and hence the sum of the weighted responses of relative prices must add up to zero.

one-month horizon and 11.5% in the long run. Panel C shows that relative price shocks—both productivity (thick blue line) and demand (thin red line)—jointly account for around 71% of the inflation forecast error at all horizons, with demand shocks accounting for 50% of the forecast error and than productivity shocks accounting for 21%.[11] The finding that relative price shocks account for a large proportion of the inflation forecasts error at all horizons is consistent with results in Reis and Watson (2010, p. 146) who report that 76% of the movements in aggregate inflation are accounted for by a relative-price index.[12] A similar result is reported by Smets et al. (2019) who find that sectoral shocks, by ways of pipeline pressures, are an important contributor to the variance and persistence of headline inflation.

The remaining panels in Figure 6 (D through R) report the contribution of relative price shocks in each sector to the variance decomposition of inflation. Panel J shows that relative price shocks to gasoline account for approximately 46% of the variance of the inflation forecast error at all horizons, with demand shocks accounting for a higher proportion of the variance (31%) than productivity shocks (15%). The contribution of gasoline demand shocks is high. We see two reasons for our estimated model to deliver this result. First, because we assume Cobb-Douglas preferences across the 15 consumption categories, expenditure shares are constant in response to sectoral productivity shocks. To the extent that the actual gasoline expenditure share comoves positively with the relative price of gasoline, our model will interpret this comovement as coming from gasoline demand shocks. Second, our model omits network effects, whereby demand for gasoline may be affected by other sectoral shocks which then feed through to the demand for gasoline. Panels Q, D, L, M, and K show that relative price shocks to finance and insurance, motor vehicles, housing and utilities, health, and other nondurables substantially contribute to the variance of the inflation (roughly 7.1%, 4.8%, 3%, 1.3%, and 2.4%, respectively). Demand shocks appear to be quantitatively more important than productivity shocks in all cases. Research based on dynamic factor models (e.g., see Boivin et al., 2009) typically finds that aggregate factors are the main driver of aggregate inflation.[13] Using a structural model with input-output interactions, Onatski and Ruge-Murcia (2013) show that macroeconomics shocks can indeed be considered factors in that they nontrivially affect most variables in the model. However, principal components analysis has a hard time replicating the macroeconomic factor space because sectoral shocks can act as aggregate shocks.

[11] The shock to the discount rate accounts for less than 0.009% of the inflation forecast error at all horizons and is not plotted in Figure 6 to save space.

[12] Note, however, that the structural interpretation of their index, which is based on a model of price setting under imperfect information, is different from our relative-price shocks because their index includes, for instance, the unanticipated component of the rate of money growth, which is an aggregate variable.

[13] Boivin et al. (2009) also emphasize differential responses of sectoral prices to aggregate and sectoral shocks. Carvalho et al. (2021) show how adding input-output linkages and labor market segmentation can help a multi-sector New Keynesian model match these patterns.

Table 5 reports the contribution to the unconditional variance of each sectoral price change of the "own" relative price shocks distinguishing between productivity (Column 1) and demand (Column 2) shocks, of the aggregate productivity shock (Column 3), and of the monetary policy shock (Column 4) . The table shows that, except for health care, the "own" productivity shock accounts for most of the variance of all sectoral price changes. The contribution of the "own" demand shock is also substantial. The contribution of the aggregate shocks varies across sectors. In particular, the aggregate productivity and monetary policy shocks respectively account for 18% and 13% of the unconditional variance of price changes in health care, but less of other sectoral price changes. The contribution of productivity and demand shocks in other sectors is negligible.[14] The finding that the sector-specific shocks account for most of the variance of sectoral price changes is consistent with results reported in Boivin et al. (2009) and Mackowiak et al. (2009) based on estimated dynamic factor models. Boivin et al. (p. 356) report that 85% percent of the monthly disaggregated inflation fluctuations are attributable to sector-specific shocks, while Mackowiak et al. (p. 82) report that the proportion of the variance in sectoral price changes due to sector-specific shocks in their median sector is 90% with a 90% confidence interval ranging from 79% to 95%. In our sample, sector-specific shocks account for between 52.1% of the variance of sectoral price changes in health care to 99.9% in gasoline and other energy goods.

It is interesting to note that there is basically no relationship between price rigidity and the proportion of the variance that is accounted for by the monetary policy shock. The correlation between the price rigidity parameters in Table 2 and the proportions in Column 4 is -0.264 and not statistically significant. In contrast, the correlation between the standard deviation of sectoral productivity shocks in Table 2 and the proportions in Column 3 is -0.513 and statistically significant at the 5% level. This result means that in sectors with less volatile productivity innovations, aggregate productivity explains a larger proportion of the variance of inflation.

5.3 Inflation and the Distribution of Relative Price Changes

Panel A in Figure 7 displays the monthly PCE inflation rate rate on the vertical axis against the share of relative price increases—or equivalently, the share of price increases greater than the inflation rate—from 1995 through 2019. A striking feature of this plot is the close empirical relationship between the two variables.[15] Panel B in the same figure plots the same relationship but based on artificial data simulated from our estimated model. Comparing both panels shows

[14] These figures are not reported to save space, but their sum can be computed by substracting the contributions in Table 4 from 100% for each sector.

[15] This empirical relationship is discussed in Wolman (2022) in relation to the high inflation observed since in March 2021, and it is examined in more detail by Hornstein et al. (2023).

that the model can account for this feature of the U.S. data. This result is due to the fact that our estimated specification matches well the behavior of category price changes and, importantly, that it does so by assigning a large role to sectoral, versus aggregate, shocks.

We now provide some intuition for Figure 7 from the perspective of the model. To begin, note that there is a simple relationship between (i) the shares of relative price increases and decreases and (ii) the average sizes of relative price increases and decreases. Because the average relative price change is zero, the ratio of the share of relative price increases to the share of relative price decreases is identical to the ratio of the average relative price decrease to the average relative price increase,

$$\Gamma\left(\Delta r^{+}\right)-(1-\Gamma)\left(\Delta r^{-}\right)=0,$$

which implies

$$\Gamma/(1-\Gamma)=(\Delta r^{-})/(\Delta r^{+}),$$

where Γ is the share of relative price increases, and Δr^{+} and Δr^{-} are the average relative price increase and decrease, respectively. Note that the way we have written these equations, the average relative price decrease is a positive number.

The key point here is that monetary policy responds—in the model and generally in the data—to economywide aggregates, as opposed to sectoral price changes. When a relative price shock hits a particular sector, the desired relative price change is accomplished mainly by a nominal price change of the same sign for that sector, so that inflation moves in the same direction (Figure 5). It's theoretically possible for monetary policy to perfectly stabilize inflation, or even to generate an upward sloping relationship between the share of relative price increases and the inflation rate. But either of these cases would require that in the face of a large relative price shock for just one sector, monetary policy generates large nominal price changes for all other sectors in the opposite direction. This seems implausible, and is not what we see in the data.[16]

Instead, we conclude that most of the time, the share of relative price increases is close to one half, and inflation is close to target. When the share of relative price increases is large, it is associated with a small share of sectors experiencing large positive productivity shocks (or large negative demand shocks), and choosing large *nominal* price decreases, which results in low inflation. When the share of relative price increases is small, it is associated with a small share of sectors experiencing large negative productivity shocks (or large positive demand shocks), and choosing large *nominal* price increases, which results in high inflation. The systematic behavior of monetary

[16] Additionally, in New Keynesian models such as the one we employ, it is generally not optimal to stabilize the price level in response to large relative price shocks, unless those shocks hit sectors in which nominal rigidities are especially large. Goodfriend and King (1997) first made this general point; Aoki (2001) provided analytical results in a two-sector model; and Eusepi et al. (2011) conducted quantitative analysis in a model similar to ours.

policy delivers these relationships as equilibrium outcomes: it is optimal for sectors experiencing changes in their desired relative price to move their nominal price in the same direction, and for other sectors to respond very little.

In order to understand the mechanism that drives these results, we perform a comparative static exercise to examine the roles of price rigidity, heterogeneity in the volatility of demand shocks, and heterogeneity in the volatility of supply shocks. Panel C in Figure 7 displays the same relation between the monthly PCE inflation rate rate and the share of relative price increases based on data simulated from a version of the model where all prices are flexible. That is, all parameters ϕ_s are set to zero while the remaining parameters are those reported in Tables 1 through 3. The close relationship between the two variables remains and we conclude that the relationship is not closely related to price stickiness or the heterogeneity in price stickiness across sectors.

These results relate to work by Balke and Wynne (2000) as follows. Compared with Ball and Mankiw (1995), whose explanation for the relationship between relative price changes and inflation relies on price stickiness, Balke and Wynne consider a flexible-price model. There are three central elements to their analysis. First, they point out that in a flexible price model, properties of the distribution of sectoral productivity growth would be reflected in the distribution of relative price changes. Second, they provide evidence that the distribution of productivity changes in fact had much in common with the distribution of sectoral price changes. These two elements are also present in our model in a more general setup where the data are allowed to determine the extent of price rigidity in each sector. Finally, they show that in a calibrated multi-sector model with flexible prices, basic properties of the empirical relationship between the inflation and the distribution of relative price changes are replicated when the model is driven by an estimated sectoral productivity process.

Panels D and E display the same relation between the monthly PCE inflation rate rate and the share of relative price increases based on data simulated from a version of the model where the standard deviation of all demand shocks (Panel D) and supply shocks (Panel E) are the same. That is, in Panel D all $\sigma^2_{\zeta,s}$ are set to the same value, namely the median of the estimates in Table 2. Similarly, in Panel E all $\sigma^2_{z,s}$ are set to the median of the estimates in Table 2. Panels D and E show that the close relationship between the two variables remains when we independently assume no heterogeneity in the volatility of demand or supply shocks. In contrast, Panel F shows that the relation is considerable weaked when we jointly assume no heterogeneity in the volatility of demand and supply shocks. Thus, we show that heterogeneity in the variance of sectoral shock innovations is important to account for the empirical relationship between relative price changes and inflation.

6. Inflation Shortfall in 2012-2019

We estimated the model over post-1994 U.S. data. Over that period, inflation averaged around 2% and was quite stable by historical standards. Since 2012, the Federal Reserve has had a formal 2% target for PCE inflation, but from 2012 to 2019, PCE inflation averaged only 1.39%. We focus here on the post-2012 period and use the model to decompose the inflation shortfall into contributions from the various estimated shocks. The shocks estimates correspond to the smoothed estimates obtained using the Kalman filter. Appendix A shows how this decomposition is carried out starting from the state-space representation of the model solution so that the indirect effect of the shocks via the endogenous state variables is taken into account.

Because mean inflation is 2%, if the model state variables were at their steady states and there were no shocks, then inflation would be constant at 2%. The model explains an episode of deviations from 2% inflation by a combination of initial state variables being away from steady state and subsequent shocks. Figure 8 presents four panels that will guide our understanding of the contribution of key shocks to the U.S. inflation rate during this period. The horizontal axis is months from January 2012 to December 2019. The vertical axis is the inflation deviation in percentage points from the inflation target of 2%.

Panel A reports the contribution of the aggregate productivity shock, the monetary policy shock, and the sum of all relative shocks (both productivity and demand) to the inflation shortfall. The contribution of the preference shock is negligible and omitted for clarity. An important observation from Panel A is that monetary policy played a limited, but consistent, role in the shortfall. On average, the shortfall due to monetary policy is 0.21 percentage points (pp). Since the average inflation shortfall was $2\% - 1.39\% = 0.61$ pp, we conclude that about one-third of the shortfall is attributable to monetary policy. Put differently, U.S. monetary policy was mildly restrictive compared with the stance that would have been consistent with the inflation target of 2%. This result also means that most of the inflation shortfall was due to aggregate productivity and relative price shocks, although their contribution varies substantially over time. In particular, the contribution of aggregate productivity shocks was only quantitatively important in the period from 2014 to 2016, and its average contribution is only 0.08 pp. The contribution of relative price shocks to the inflation shortfall is quantitatively important from most of the sample, and particularly large in 2014-2016, when the shortfall was the largest.

Panel B differs from Panel A in that it separately reports the sum of all productivity shocks and the sum of all demand shocks, in addition to the aggregate productivity shock and the monetary policy shock. This panel shows that relative-price productivity shocks made a consistent but limited

contribution to the inflation shortfall, reaching 0.4 pp in early 2015, but that relative-price demand shocks contributed even more to the shortfall, reaching 0.85 pp in October 2015.

Panel C attempts to shed some light on the contribution of different sectors by reporting the contribution of the joint productivity and demand in each sector, having excluded those that played a limited role so as not to crowd the picture. In addition to aggregate productivity and monetary policy we reported earlier, this panel reports the sum of productivity and demand shocks in health care and gasoline and energy goods. Health care shocks played a substantial role initially, specially in 2013 and 2014 when its contribution reached 0.2 pp (August 2013). On average, the contribution of the health care shocks is about 0.08 pp. Gasoline shocks are the most quantitatively important relative price shocks to account for the shortfall, and in the period 2015-2016 account (along with aggregate productivity) for most of the shortfall. Comparing Panels A and C shows that the component of the relative price shocks in that accounts for the shortfall in Panel A are relative price shocks to gasoline and energy goods.

Finally, Panel D decomposes relative price shocks to health care and gasoline into their respective productivity and demand shocks. This panel shows that productivity and demand shocks to gasoline were by far the most important relative price shock. The quantitative contribution of gasoline productivity shocks to the inflation shortfall is comparable to that of monetary policy. The quantitative contribution of gasoline demand shocks to the shortfall is comparable to the aggregate productivity shock. Once we decompose relative price shocks in health care into productivity and demand shocks we can see that both played a role in the shortfall but separately not a quantitatively large one.

In summary, most of the inflation shortfall in 2012-2019, and in particular in the period 2015-2016 when the shortfall was the largest, is attributable to aggregate productivity shocks and relative price shocks (both productivity and demand) to gasoline and other energy goods. On average, about 1/3 of the shortfall is attributable to monetary policy. The monetary policy contribution was stable over time, even in late 2016, which coincided with the Fed's increase in interest rates. While that rate increase was gradual by historical standards, according to our estimated model, it represented a contractionary policy shock so that overall, U.S. monetary policy during this period was mildly restrictive compared with the stance that would have been consistent with the inflation target of 2%.

7. Inflation Surge in 2020-2023

We now use our estimated model to interpret the behavior of U.S. inflation in the period immediately after our estimation sample; that period corresponds to the COVID-19 pandemic and its

aftermath, when inflation was at first volatile and then consistently far above the Fed's 2% target. Recent work that studies the macroeconomic implications of the pandemic include Baqaee and Farhi (2022), Guerrieri et al. (2022), and Woodford (2022). Guierreri et al. focus on the effects of asymmetric shocks that affect one sector more than another in an economy with complementarities in consumption. and show that a supply shocks like this acts as a demand shock as well because workers are out of a job and aggregate demand falls. However, contrary to our analysis, which focuses on inflation, their work is concerned with the transmission of an asymmetric (COVID) shock in economies with complementarity in production (Baqaee and Farhi, and Guerrieri et al.) or a network payments structure (Woodford). Closer to our work is the paper by Gagliardone and Gertler (2023), who study the inflation surge by decomposing the contributions of sectoral and aggregate shocks with a focus on only two sectors, namely oil and non-oil. We work with a richer environment composed of 15 sectors, one of which is oil, and construct a finer disaggregation that shows that shocks to sectors other than oil (e.g., motor vehicles) are important to understand the inflation surge.

Because it interprets the data through the lens of the estimated model, this analysis assumes that the U.S. economy has remained in a rational expectations equilibrium involving local fluctuations around a steady state with 2% inflation. One might respond sceptically that we are assuming the answer to the most important question: has the U.S. economy remained in that equilibrium, or has the Fed's behavior deviated from its previous rule to such an extent that private agents no longer perceive that rule to be in place? We do not dispute the importance of that question, and in fact see our work as contributing to an answer: under the assumption that inflation has remained anchored, we provide estimates of the contributions to observed inflation from monetary policy and sectoral shocks. An evaluation of those estimates based on independent information can then help in assessing whether inflation has in fact remained anchored.

As before, we decompose observed inflation into the contributions of the various shocks. The data is now outside our estimation sample, but the procedure is otherwise identical. Note that this procedure also yields a counter-factual policy analysis. Figure 9 presents selected elements of the decomposition of the inflation surge post-pandemic. The figure uses data though June 2023 and, thus, capture the pandemic and the high inflation months that followed. As before, the figure presents four panels where the horizontal axis is months from January 2020 to June 2023 and the vertical axis is annual inflation in percentage points.

Panel A reports the contribution of the aggregate productivity shock, the monetary policy shock, and the sum of all relative (productivity and demand) shocks to inflation. (The contribution of the preference shock is negligible and omitted for clarity). First note that monetary policy was

roughly consistent with the 2% target during the pandemic, with the large increase in the money supply implement by the Federal Reserve able to stave off the large drop in velocity during this period. After the pandemic, the monetary policy shock can account for at most 1 pp of annual inflation in mid-2022 (over and above the inflation target of 2%). Since inflation in this period was roughly 6% (that is 4 pp above the target), we conclude that the monetary policy shock accounts for approximately 1/4 of the inflation surge. Aggregate productivity played limited role in the decrease in inflation during the pandemic and account for slightly less than 1 pp of the inflation surge after the pandemic. Thus, a clear message from Panel A is that relative price shocks (both demand and productivity) accounted for most of the deflation during the pandemic and for more than 1/2 of the inflation surge in its aftermath.

Panel B reports separately the sum of all supply and demand shocks, in addition to the aggregate productivity shock and the monetary policy shock. This plot shows that relative productivity shocks played a role comparable to the aggregate productivity shocks reaching its peak in early 2022, around the time that Russia invaded Ukraine, but decreasing fast thereafter. The plot also shows that the largest contributor to inflation surge were relative-price demand shocks. At its peak in mid-2022, demand shocks contributed close to 1/2 of the surge.

Panel C attempts to shed some light on the contribution of different sectors by reporting the contribution of the joint supply and demand in each sector. (We excluded those sectoral shocks that played a limited role so as not to crowd the picture.) In addition to aggregate productivity and monetary policy that we reported earlier, this panel reports the sum of supply and demand shocks in motor vehicles, housing, and gasoline and energy goods. Comparing Panels C and A shows that while the deflation was strongly driven by gasoline shocks, the post-pandemic surge was broad-based and encompassed many sectors with these three sectors being the most prominent. Panel D discomposes relative price shocks to motor vehicles, housing, and gasoline and energy goods into their respective productivity and demand shocks and makes the point that both types contributed to the surge with demand and productivity shocks to gasoline being important in 2022 and the housing demand shocks becoming increasingly important in 2023.

In summary, according to our estimated model, gasoline shocks drove the sharp drop in inflation early in the pandemic with monetary policy being entirely consistent with the 2% inflation target. The contribution from monetary policy shocks and aggregate productivity shocks to the post-pandemic inflation surge is limited and most of it is attributable to relative price shocks with shocks to motor vehicles, housing, and gasoline being the most prominent.

8. Conclusions

We set out to evaluate the contribution of monetary policy and sectoral shocks—relative price shocks—to the behavior of inflation and we found their contribution to be very large indeed. Monetary policy accounts for only about 11% of the unconditional variance of inflation, while sectoral productivity and demand shocks account for about 70%. Approximately one-third of the inflation shortfall in 2012-2019 is attributable to monetary policy with the attributable to aggregate productivity (only initially) and sectoral shocks, notably to gasoline and health care. We also find that monetary policy was roughly consistent with the 2% target during the pandemic and accounts for only 1/4 of the inflation surge thereafter, with sectoral shocks—in particular, to gasoline, motor vehicles, and housing—accounting for most of the surge. To be clear, we are not claiming that inflation is always and everywhere a relative-price-shock phenomenon. Rather, the lesson is simply that if monetary policy has credibility and behaves in a way that delivers stable inflation, then the inflation fluctuations that remain seem to be driven by sectoral shocks.

Appendix A: Inflation Decomposition

The linearized solution of the model takes the state-space form

$$X_{t+1} = HX_t + \vartheta_{t+1}, \tag{A1}$$

$$Q_t = GX_t, \tag{A2}$$

where (A1) is the state equation, (A2) is the observation equation, X_t and ϑ_t are $(4S+5)\times 1$ vectors with S being the number of sectors, H is a $(4S+5)\times(4S+5)$ matrix with the parameters of the exogenous shock processes and the coefficient of the decision rules of the endogenous predetermined variables, Q_t is a $J\times 1$ vector of observable variables, and G is a $J\times(4S+5)$ matrix whose elements are the coefficients of the decision rules of the observable variables.

To develop intuition, imagine a model with no endogenous state variables in X_t. In that case, (A2) would provide the exact decomposition of each variable in Q_t in terms of all exogenous shocks at every point time. In our more general model, X_t contains endogenous state variables that depend on current and past exogenous shocks in the manner we make precise now. Decompose X_t in (A1) as a $(2S+3)\times 1$ vector with the exogenous shocks, Z_t, and a $(2S+2)\times 1$ vector with the endogenous state variables, K_t,

$$X_{t+1} = \begin{bmatrix} Z_{t+1} \\ K_{t+1} \end{bmatrix} = \begin{bmatrix} H_{11} & 0 \\ H_{21} & H_{22} \end{bmatrix} \begin{bmatrix} Z_t \\ K_t \end{bmatrix} + \begin{bmatrix} \omega_{t+1} \\ 0 \end{bmatrix}, \tag{A3}$$

where H_{11}, H_{21}, and H_{22} are conformable matrices with the parameters of the exogenous shock processes (H_{11}) and the coefficient of the decision rules of the endogenous predetermined variables (H_{21} and H_{22}). Note that (A3) implies

$$Z_t = H_{11}Z_{t-1} + \omega_t, \tag{A4}$$

$$K_t = H_{21}Z_{t-1} + H_{22}K_{t-1}. \tag{A5}$$

Rewrite (A2) as

$$Q_t = \begin{bmatrix} G_1 & G_2 \end{bmatrix} \begin{bmatrix} Z_t \\ K_t \end{bmatrix} = G_1 Z_t + G_2 K_t, \tag{A6}$$

where G_1 and G_2 are respectively conformable matrices with the coefficients of the exogenous shocks and the endogenous predetermined variables in the decision rules of the observable variables. Iterating backwards τ periods in (A5) and using (A4) allow us to write

$$Q_t = G_1 Z_t + G_2 \sum_{j=0}^{\tau} (H_{22})^j H_{21} Z_{t-1-j}. \tag{A7}$$

Equation (A7) decomposes exactly the observable variables in Q_t in terms of current and past exogenous shocks and is the basis of the inflation decompositions reported in Sections 5 and 6 in the text.
