Abstract

Do banks price their borrowers' exposure to climate transition risk? I find that in the E.U., firms negatively exposed to climate transition risk face higher lending rates by banks specialized in their borrowers' industry. However, I also find evidence of lower lending rates to more exposed firms after an oil supply news shock relevant for energy-intensive firms, especially during periods of high aggregate financial stress. Interpreting bank specialization as a source of heterogeneity in costs of private information acquisition, I develop a bank lending model with competitive lending, costly information acquisition, and non-Bayesian belief updating. Because of screening, specialized banks can better distinguish between borrowers' risk exposure, resulting in relatively higher lending rates to more exposed firms. However, this interest rate differential decreases in favor of more exposed borrowers when banks underreact to relevant public information. This effect is more pronounced during periods of poor borrower quality or increased financial stress. These results imply that lowering banks' cost of acquiring firm-level transition-risk exposure information is crucial to reduce green firms' financing costs, even when there is high quality public information and communication about decarbonization.

1. Introduction

The financial risks associated with climate change have intensified, underscoring the critical role of private financial markets in funding the transition to a low-carbon economy (Carney 2021; Yellen 2021; Hale 2023). This "green transition" could result in significant losses for firms and investors if carbon-intensive assets are revalued or technological advances render carbon-heavy operations unproductive. Such risks, known as climate transition risks, add uncertainty to the lending landscape. Yet, evidence suggests that many banks continue to disregard these factors in their loan pricing and maintain substantial lending to high-emission sectors (Kirsch et al. 2021). Climate stress-testing studies reveal that banks are meaningfully exposed to transition policies, particularly sudden carbon price increases, through both credit and market risk channels (Acharya et al. 2023; Jung et al. 2023). Addressing this exposure may require systemic changes, including better climate-risk disclosure and standards that enable banks to assess and price transition risks more effectively.

In this paper, I take an information-centric approach to understanding how banks price corporate exposure to climate transition risk. I provide empirical evidence that specialized banks, through their industry-specific expertise, can better price regulatory aspects of climate transition risk. Further, I examine if banks adjust their pricing decision in response to an oil supply news shock relevant to energy prices and, therefore, energy-intensive firms. I explain the role of bank specialization in a model of imperfect and costly screening and underreaction to costless public information within a competitive bank lending framework. I show that specialized banks can better distinguish between differently exposed borrowers than non-specialized banks. Yet, if banks underreact to public information, the interest rate differential between more and less exposed borrowers narrows, especially during periods of financial stress. Thus, the model highlights two critical mechanisms through which banks can effectively price climate risk in lending contracts – (i) information acquisition and (ii) accuracy-motivated belief updates given the availability of new information.

To establish the role of bank specialization in pricing firm-level climate transition risk, I start with an empirical analysis using syndicated lending data for non-financial firms across multiple countries. I use firm-level emission intensity, and forward-looking measures of policy and technological transition risks from public companies' earnings calls by Sautner et al. (2023), as proxies for firm-level exposure to transition risk. These measures allow me to test whether higher firm-level transition risk exposure is associated with higher lending rates, focusing on whether specialized banks are more responsive to these risks. Furthermore, to examine the potential effects of heterogeneity in policy environments aimed at driving sustainable activities, I conduct separate analyses for firms headquartered in the U.S. and those headquartered in the E.U.

I find that, on average, banks do not adjust lending rates based on firms' transition risk expo-

sure across the sample if exposure to transition risk is measured by emission intensity and negative exposure to green technologies. However, forward-looking negative exposure to climate regulations correlate with higher lending rates (measured by all-in-spread-drawn (bps)). When examining forward-looking exposure to climate regulations, I observe regional differences. For firms headquartered in the E.U., greater regulatory exposure is associated with a lower lending rate. In contrast, for U.S.-based firms, higher exposure to climate regulation is associated with a higher lending rate.

Without mandated and standardized information disclosure of firm-level exposure to climate transition risks, it is challenging for banks to acquire information about their borrowers' sustainable activities (or lack thereof). Specialized banks, however, may possess an informational edge over non-specialized banks due to their industry-specific expertise (Paravisini et al. 2023; Blickle et al. 2023, 2024; Degryse et al. 2024). Indeed, I find that across the entire sample, specialized banks generally charge higher lending rates to firms with high emission intensity, suggesting they may perceive these firms as riskier. This effect is particularly evident for E.U.-based firms negatively exposed to climate regulations, with specialized banks charging them higher interest rates. Interestingly, this pattern does not hold for U.S. firms, for which the specialized banks appear less sensitive to climate regulatory exposure. This difference between E.U. and U.S. firms can be attributed to the consistent effort towards sustainability disclosure and decarbonization policies in the E.U.

Next, I evaluate whether specialized banks respond to signals about firms' vulnerability to fossil-fuel shocks and transition risk. I use oil supply news shocks as proxies for public signals on disorderly transition risk (Känzig 2021). These shocks, relevant in the absence of carbon pricing regimes across most countries in the sample, offer insights into banks' responses to energy-related vulnerabilities[1]. Furthermore, previous literature has pointed out the negative effect of oil supply shocks on equity returns of firms in industries facing an elevated risk from carbon transition, highlighting the role of these shocks as an important signal to be accounted for investors and lenders. This analysis reveals mixed results. U.S.-based firms with higher emission intensity face lower interest rates from specialized banks one quarter after an oil supply news shock. This trend is also consistent across the entire sample for high emission-intensity firms. In contrast, E.U. firms with high emission intensity or negative climate regulatory exposure do not face significantly higher lending rates post-shock.

Finally, I examine whether high aggregate financial stress preceding the loan contract is associated with specialized banks charging lower interest rates to negatively exposed firms. As a measure of

[1] An aggregated "energy input" in a firm-level production function is a convex combination of energy from fossil fuels and that from renewable sources (Hassler et al. 2016). A transition shock could be a carbon tax, leading to a decline in the per-unit return on physical capital for a carbon intensive firm. In a transition scenario involving a policy shift towards energy efficiency, a firm with lower levels of energy-efficient technology would receive smaller returns from an "energy-efficient technology" shock than a more energy-efficient firm (Hassler et al. 2012). The lenders' payoff from financing these firms' investment projects would then be adversely affected. The recent TFCD report by Citibank has shown a high exposure to transition risk arising from funding oil & gas projects and automobile manufacturers (*Finance for a climate-resilient future* 2020).

financial stress, I use the Financial Stress Index (FSI) by the Office of Financial Research (OFR) (Bejarano 2023) for the U.S., and I use the Country-Level Indicator of Financial Stress (CLIFS) (Duprey et al. 2017) for the E.U. I find that following periods of high financial stress, specialized banks do not charge significantly higher rates to U.S. and E.U. firms with high transition risk exposure after an oil supply news shock.

To summarize, three key findings emerge from this analysis. First, banks specialized in the borrower's industry incorporate certain transition risk factors - emission intensity and negative climate regulatory exposure - into their lending decisions. Second, following an oil supply news shock, this effect is insignificant or only shows up after a significant lag. The role of bank specialization underscores the informational advantage of industry-specific expertise, enabling banks to assess their borrowers' carbon exposure and decarbonization plans. However, it also reveals an inertia in responding to relevant public signals about borrowers' vulnerability to volatility in the global fossil-fuel markets. Third, the pricing of transition risk by specialized banks becomes weaker after a period of financial stress.

It is essential to understand whether the cost of acquiring information about borrowers' industry exposure and banks' response to public signals about transition risk explain the interest rate differentials between more and less exposed firms to understand the empirical results. Central banks and regulatory authorities conducting climate stress tests have highlighted significant information gaps lenders face in assessing their transition risk exposure. These gaps arise mainly from the lack of standardization (EBA 2021) and the absence of comprehensive frameworks for estimating borrowers' emissions and transition risk management (FRB 2024). Information frictions related to transition risk are further exacerbated by deep uncertainties that characterize climate risk. Models that are not forward-looking and focus more on the past emission performance of firms will not comprehensively capture these risks (Monasterolo 2020).

Previous research on financial intermediaries has shown how lower screening costs and better monitoring reduce uncertainty about the ex-ante qualities of borrowers, thus positively affecting aggregate investment (Gertler and Bernanke 1989; Holmstrom and Tirole 1997; Levine 2005). However, screening is both costly and imperfect, and heterogeneous screening capacities across lenders in a perfectly competitive environment can result in informational advantages for the lender who screens more.

I develop a model of costly screening of two borrowers differentially exposed to climate transition risk within a competitive lending framework. Both borrowers are similar in all aspects; the key difference between them is the probability of their projects' success. Given a potential transition risk shock, borrowers more exposed to transition risk have lower expected project returns. To capture the

informational advantages of bank specialization in the borrower's industry, I consider two banks - (i) specialized (acquires costly private information about the borrowers' quality) and (ii) unspecialized (uninformed: does not acquire any private information due to prohibitively high information acquisition costs).

Lenders should update their loan repayment expectations for more exposed borrowers with the changing dynamics of climate transition risk caused by the development of energy-efficient technologies, scientific evidence, or frequent weather events. However, belief updates regarding risks from climate change often lag due to factors like model uncertainty, unpredictable weather patterns, and fluctuating policy measures, making it challenging for expectations to converge to the true distribution of risks (Kelly and Kolstad 1999; Kelly and Tan 2015). Additionally, backward-looking expectations could severely underestimate the tail risks related to climate change (Bolton et al. 2020). Neglecting relevant information and placing greater weight on past information while updating expectations about borrowers' transition risk exposure may play a critical role in shaping loan contract terms and adversely influencing the debt-financing costs for green firms [2] [3].

I incorporate this feature of climate-change related expectation formation into the model by allowing the banks to symmetrically update their beliefs in response to a costless and imperfect public signal about the borrowers' transition risk exposure. This belief-updating process follows a non-Bayesian framework (Epstein 2006). The lenders' updated beliefs are a weighted linear combination of their "priors" (i.e., their beliefs before receiving public signals) and the Bayesian posterior after they observe the public signal.

This structure of belief formation is "accuracy-motivated"[4]. The "prior" beliefs play no role in the evaluation of the new information. However, how the lender weighs their Bayesian posterior relative to their prior beliefs may affect the subjective posterior beliefs. Consequently, there are three possible outcomes from updating: (i) no update, (ii) learning in the direction of the new information, and (iii) learning in the direction opposite to the new information (Druckman and McGrath 2019). I focus on the first two outcomes in my model and provide three theoretical results that establish the role of

[2]Research on climate risk perception employs surveys and secondary data, highlighting evidence for partial alignment with Bayesian learning and the representativeness heuristic, with individuals assigning more weight to prior beliefs amidst higher uncertainty relating to information about climate change (Cameron 2005; Deryugina 2013). Using a county-year panel from the Yale Climate Beliefs survey, I provide empirical evidence that after controlling for county-level demographics, median household income, and political beliefs, perceptions about exposure to damages from global warming increase after individuals witness a state-level 'Billion-Dollar Disaster'. However, these perceptions are still strongly anchored to 'prior' beliefs or beliefs recorded six years before the billion-dollar disaster (Appendix C).

[3]The representativeness heuristic emphasizes the overweighting of recent observations during belief formation (Kahneman and Tversky 1972). This bias is linked to Bayesian learning and diagnostic expectations, which explain business cycles (Baley and Veldkamp 2021; Bianchi et al. 2021) and pre-crisis market behavior (Krishnamurthy and Li 2020). Investors often underreact to initial negative signals but overestimate downturn risks after persistent bad news (Bordalo et al. 2018; Gennaioli et al. 2015). A similar mechanism - the neglect of risk - could be the reason that climate risk is underpriced by the financial markets, as noted by central banks worldwide (NGFS 2019).

[4]The lender evaluates new information so that their updated beliefs accurately estimate the true distribution, as opposed to "directed motivation" where the individual updates their beliefs to arrive at a pre-determined conclusion, which their "prior" beliefs may influence.

private information acquisition and underreaction to costless public information in determining the interest rate differentials between more and less exposed borrowers.

First, I compare the expected interest rates charged after the lenders receive public signals about borrower quality. In equilibrium, borrowers marked as low exposure (high quality) from both information sources face lower interest rates, while those marked as high exposure (low quality) by either source pay higher rates. When both information sources signal high exposure to climate transition risk, the interest rate charged is substantially higher. This result aligns with specialized banks' informational advantage, enabling them to distinguish more accurately between borrowers and charge higher interest rates to high-risk borrowers.

However, as the lenders' underreaction (and therefore the weight they give their prior beliefs) increases, at any given level of information acquisition by the specialized lender, the expected interest rate differential decreases in favor of more exposed borrowers. The decline in this differential is sharper for higher quality public information.

In my second theoretical result, I show that a perfectly Bayesian specialized lender significantly incorporates medium-to-high-quality public information with a lower dependence on private information. The quality of public information and the degree of underreaction influence the specialized bank's optimal level of private information acquisition. Public information allows the uninformed lender to make their interest rate offer more competitive for high-quality borrowers. Consequently, it can erode the specialized lender's informational advantage. As the lenders' underreaction increases, the informational advantage provided by the private information increases as public information is ignored by both lenders. As a result, even with high-quality public information, optimal private information acquisition by the specialized lender increases with under-reaction.

Third, I examine how the interplay between private information acquisition and underreaction to public information impacts interest rate differentials, especially when borrower quality is low. During periods of poor average borrower quality, the reliance on private information acquisition for the specialized lender is high. Therefore, as underreaction increases, there is a sharp decrease in the interest rate differentials between more and less exposed firms despite high-quality public information. This effect becomes weaker as average borrower quality improves and the threshold of underreaction, beyond which interest rate differentials decline, increases. This implies that, during periods of poor average borrower quality, even a minor rise in underreaction can result in a sharp decline in the interest rate differential between more and less exposed borrowers. This result validates the empirical evidence on the pricing of transition risk exposure during periods of high financial stress in the economy.

The above results highlight how, during periods of high financial stress, the pricing of transition

risk might be even weaker, obstructing decarbonization financing by keeping the cost of debt high for more energy-efficient or green firms. Underreaction to public information increases dependence on private information, which is influenced by the marginal cost of private information acquisition.

These results have relevant policy implications. Standardized climate disclosure frameworks and climate transition stress tests would provide lenders with a better understanding of their borrower's emissions and trajectory towards decarbonization, lowering information costs for lenders and supporting green transition financing even during episodes of high financial stress. Contemporary studies on the impact of climate supervisory tests record empirical evidence supporting these implications for loan pricing as well as credit allocation. Banks subjected to the French bank climate pilot exercise charged higher interest rates for brown borrowers, with the stress tests providing incremental reduction in climate transition-related information asymmetries for the banks (Fuchs et al. 2024). Similarly, banks subjected to the ECB Single Supervisory Mechanism (SSM) reallocated credit to greener firms (Aiello 2024).

Related Literature: This paper expands upon two distinct strands of literature. First, I examine the extent to which climate transition risk considerations play a role in corporate bank lending decisions. Second, I reconcile the empirical analysis with a theoretical model of heterogeneous information acquisition costs and underreaction to public information in a competitive bank lending setup.

The main channels of transition risk can be summarized into (i) policies such as carbon taxes or changes in financial regulations that drive emission reductions, (ii) technological developments that increase the costs of fossil-fuel extraction or decrease those of renewable energy generation (iii) behavioral changes among agents in financial markets or in the adoption of green behaviors (Dikau and Volz 2018; Monasterolo 2020; Semieniuk et al. 2021). There has recently been substantial expansion in empirical research on the degree to which the lending rates charged by banks are associated with the environmental concerns linked to a borrower, either because of an adverse climate-related or ESG incident or high carbon emission intensity. Both these factors represent a reputational risk or firm exposure to environmental policies that would have an adverse impact on the profitability of emission-heavy firms (Hrazdil et al. 2020; Ehlers et al. 2021; Ivanov et al. 2023)[5].

While not necessarily focused on pricing decisions, some studies have also discussed the salience of public events that strengthen willingness to decarbonize, such as the Paris Agreement and COP21, to the credit allocation between carbon-intensive and non-carbon-intensive firms (Delis et al. 2019; Reghezza et al. 2021). There is also increasing focus on the exposure of firms to disruptions in green technology and on how banking concentration and bank exposure to negatively exposed firms play a role in credit reallocation between firms positively and negatively exposed to green technological

[5]Environmental, Social, and Governance – ESG criteria are used to inform investors about the degree to which a firm is environmentally and socially conscious and its governance is transparent and accountable.

developments (Degryse et al. 2020; Mueller and Sfrappini 2022).

While the aforementioned empirical studies are relevant because they document the empirical facts regarding changes in bank behavior given an increase in climate change policy discussions, they do not necessarily identify all the channels through which transition risk might affect banks' lending decisions. Unlike default lending information, which is verifiable by both the borrower and the lender, information on firms' exposure to climate risk is not and therefore comes under the category of 'soft' or 'subjective' information (Liberti and Petersen 2019).

I add to the empirical literature on the pricing of transition risk by examining the role of bank specialization in the borrower's industry as a source of informational advantage when pricing borrower exposure to both the regulatory and the technological aspects of transition risk . Bank specialization provides a marginal improvement in information acquisition in an environment where standardized emission and sustainability disclosures are not the norm. Furthermore, I incorporate oil supply news shocks as global shocks relevant to all firms, regardless of the state of environmental policies in country in which they are headquartered. Álvarez-Román et al. (2024) take a similar approach to understand the association between credit allocation and physical risks. They examine firm-level credit allocation after wildfires in Spain and show that local banks leverage their geographical proximity to firms as soft information, which allows them to decrease credit to the firms by lesser extent than the more diversified nonlocal banks.

I also build upon the literature on competitive information acquisition by lenders. Theoretical frameworks of lending decisions by competitive banks with heterogeneous information acquisition capacities highlight how a reduction in the costs or uncertainty associated with information acquisition benefit high-quality borrowers through lower interest rates (Hauswald and Marquez 2003; Karapetyan and Stacescu 2014; Banerjee 2005).

I extend the existing theoretical frameworks by highlighting the impact of underreaction to public signals on private information acquisition and the potential failure of lenders to incorporate relevant public information about exposure to green technologies and policies during times of high credit risk. The theoretical model provides a tractable framework to show how public information creates interest-rate differentials between less and more exposed firms provided banks choose to update their beliefs about climate risk.

The rest of the paper is structured as follows: Section 2 discusses the empirical framework and results to motivate the theoretical framework for information acquisition and underreaction to public information. Section 3 describes the setup of the theoretical model and the equilibrium of the lending game in the second period with non-Bayesian updating. Finally, Section 4 concludes.

2. Empirical evidence: Bank specialization and pricing firm-level transition risks

This section presents the empirical analysis of syndicated bank loans and firm-level transition risk exposure. I begin with describing the data sources and descriptive statistics for syndicated lending and firm-level controls (Section 2.1) and measures of firm-level transition risk exposure (Section 2.1.1). Next, I define and create a measure of industry-specific bank specialization (Section 2.1.2) and provide descriptive statistics for loan terms and borrower characteristics for loans made by specialized banks. Following this, I describe the oil supply news shock (Section 2.1.3).

I proceed by specifiying the empirical specification to examine if (i) loans made by specialized banks with higher exposure to climate transition risk have higher interest rates (ii) specialized banks adjust their lending rates one-to-four quarters after an oil supply news shock for more exposed firms and (iii) lending rates charged by specialized banks for more exposed firms change after a period of high financial stress post-oil supply news shock (Section 2.2). I present the empirical findings in Section 2.3.

2.1. Data

I rely on three data sources: (i) syndicated loan data from Dealscan (ii) Scope 1 and 2 carbon emission intensity from Trucost and (iii) Green technology-related exposure, and climate regulation exposure from Sautner et al. (2023) for the periods 2010 - 2022 respectively[6]. I restrict the analysis to loans made by banks and borrowers in the non-financial sector for whom I find firm annual balance-sheet variables in Compustat[7]. I exclude loans not made by the lead arranger. The resultant sample consists of 59,630 loan-level observations with emissions data across 2,031 firms in 64 countries and 65,633 loan-level observations with climate risk measures across 2,106 firms in 64 countries. A detailed explanation of the sample composition is in Table A1.

To measure the effect of climate risk exposure on loan pricing, I use the All-In-Spread-Drawn (AISD) variable from Dealscan. AISD measures the amount paid by the borrower over LIBOR for each dollar drawn down, with the annual (or facility) fee paid to the lender(s). I control for loan amount, tenor maturity, collateral requirements and presence of covenants in the loan contract. Firm-level controls from Compustat include log of total assets in US dollars, leverage ratio, ratio of capital

[6] I merge loan-level data with climate risk measures from Sautner et al. (2023) by first combining the Dealscan sample with the Chava and Roberts (2008) Dealscan-Compustat link and then using the merged sample to link to the Sautner et al. (2023) firms using gvkey as an identifier. I merge loan-level data with firm-level emissions data in Trucost in two steps. I first do an exact merge using the borrowers' gvkey and company name using the Dealscan-Compustat link. I use multi-variable fuzzy matching techniques for the unmatched firms by approximately matching borrower name and borrower parent name in Dealscan to entity names in Dealscan.

[7] I distinguish between bank and non-bank lenders using the classification in the existing literature (Aldasoro et al. 2023; Elliott et al. 2021).

expenditure to total assets, and ratio of EBITDA to total assets. Summary statistics for loan- and firm-level variables for the entire sample are in Table 1.

2.1.1. Measures of transition risk exposure

Trucost provides detailed information on Greenhouse Gas (GHG) emissions for a vast selection of firms. I use Scope 1 and Scope 2 GHG emission intensity (measured in metric tonnes per USD) for the fiscal year previous to the year of the lending contract[8]. Tables 2 summarizes the lending terms and balance-sheet variables for firms with emissions above and below the median emissions. The average AISD for firms with scope 1 and 2 emission intensity greater than the median emission intensity are lower than the sample average, implying that high emission firms are not necessarily facing higher lending rates than the rest of the sample, nor are they receiving a smaller credit amount.

Data on emissions and emission intensity are backward-looking measures of transition risk exposure, available only for a limited set of companies. They could potentially be a noisy measure of risk considering the presence of 'climate enabler' firms which might have higher emissions to support the transition to a greener economy. Sautner et al. (2023) provide a comprehensive alternative by constructing time-varying measures of firm exposure to climate change using transcripts of quarterly earnings conference calls of publicly-listed firms. They distinguish between exposure to and the sentiment and uncertainty associated with physical events, regulatory shocks, and opportunities arising from developments in renewable energy and green infrastructure in the transcripts of the conference calls, as well as the analyst Q&A sessions. Table 3 shows the descriptive statistics for lending terms and balance-sheet variables for the firms with negative exposure to technological developments related to climate transition in the year of the lending contract, and Table 4 shows the descriptive statistics for firms with negative exposure to climate regulations.

Similar to high emission firms, firms with negative regulatory and technological exposure do not face a higher average lending rate relative to the sample. However, firms with negative exposure to climate-related technologies face a higher average lending rate than firms with negative exposure to climate-related regulations or firms with higher emissions. Firms with higher emissions also have higher negative exposure to climate-related regulations relative to the rest of the sample.

[8]Scope 1 Greenhouse Gas (GHG) Emissions are direct emissions from sources owned or controlled by the entity. Scope 2 GHG emissions are emissions from generation of purchased electricty used by the entity for operations/productions. I refrain from using estimated Scope 3 GHG emissions because of the noise in estimates from third-party providers. Emission intensity is calculated as the amount of emissions (measured in CO2 equivalent units) per unit of the entity's revenue (which indirectly measures the entity's scale of output). Emission intensity is a better measure of carbon efficiency of a firm since it accounts for output-emission relationship, and provides more information about the carbon efficiency of the entity than absolute emissions. It is important to note that a decrease in emissions intensity does not necessarily translate in reduction in overall emissions.

2.1.2. Bank specialization and informational advantage

In order to reduce the probability of selecting high-risk borrowers, banks theoretically rely on multiple sources of screening and monitoring to acquire information about their borrowers. Recent literature discusses specialization of the bank in lending to a particular industry as a source of information acquisition, possible through repeated lending to individual borrowers as well as repeated lending to certain industries to gain an understanding of the performance and profit margins of an average firm in that industry (Paravisini et al. 2023; Blickle et al. 2023; Giometti et al. 2024). Bank specialization in their borrowers' industries can therefore be associated with lower information acquisition costs, given the high cost of shifting businesses from the industry the bank specializes in, to an industry within which the bank is not specialized.

I construct a measure of bank specialization, $S_{b,j}$ in a particular industry j (across NAICS 2-digit industry classification) at time t as bank b's share of credit in industry j at time t relative to the overall share of credit to industry j at time t, calculated for the year preceding the loan contract origination (Paravisini et al. 2023; Blickle et al. 2023; Giometti et al. 2024):

$$S_{b,j,t} = \frac{\frac{\sum_{i \in j} Loan_{b,i,t}}{\sum_j \sum_{i \in j} Loan_{b,i,t}}}{\frac{\sum_{i \in j} Loan_{i,t}}{\sum_j \sum_{i \in j} Loan_{i,t}}}$$

This measure of specialization captures the relative informational advantage a bank might have in lending to a specific industry, while also allowing the bank to be specialized in multiple industries and multiple banks to be specialized in an industry at the same time. The degree of bank specialization for loans in the entire sample, for firms with high emission intensity, as well as for firms with negative climate regulatory and green technological exposure is summarized in tables 1, 2, 4, and 3 respectively.

2.1.3. Response of specializing banks to an oil supply news shock

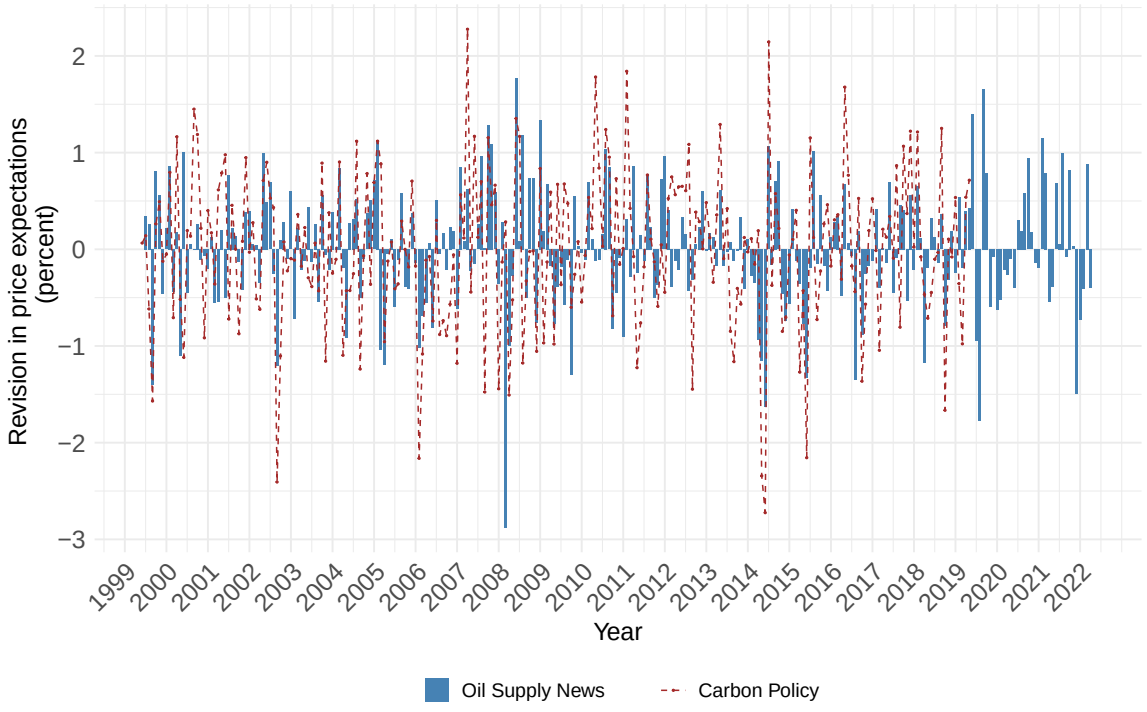

While firm-specific environmental disclosures provide an estimate of the firm's exposure to transition risk, shocks to aggregate transition risk provide a publically available dimension of information based on which lenders can adjust their expectations of firms' profitability. However, most news about transition risk is country or industry-specific, and usually centers around regulatory shocks. An informative public signal should be related to all aspects of transition risks[9]. Transition risk shocks are often defined as a disorderly jump in carbon prices.

In the absence of carbon pricing mechanisms in most countries, I use the oil supply news shock

[9]The Paris Agreement led landmark shift in public attention to climate change. However, it did not lay down specific guidelines for financial institutions regarding the path to financing of decarbonization-friendly projects

series from Känzig (2021) as a proxy for public signals about possible transition risk exposure. The estimated oil supply news shocks are associated with changes in oil supply expectations, which further leads to a significant increase in oil prices, and therefore, energy prices. By affecting energy prices they also present significant implications for the profitability of energy-intensive firms. Moreover, negative effects of unanticipated disruptions in oil supply on equity returns have been recorded for high transition risk exposure firms such as coal production firms, as well as firms in the automobile, transportation equipment, and chemical products sectors (Kilian and Park 2009). Figure 1 shows how the movement in the oil supply news shock series moves with periods of significant volatility in the oil and gas market, along with the movements in carbon policy shocks as estimated in Känzig (2023).

FIGURE 1. Oil supply news shocks

Source: Oil supply news shock (Känzig 2021); Carbon policy shock series (Känzig 2023)
Note: Carbon policy shocks are estimated using changes in the EUA futures prices in windows around carbon regulatory events associated with higher energy prices.

2.2. Empirical specification

I estimate the following regression to examine whether banks price firms' transition risk exposure as reflected in their Scope 1 and Scope 2 emission intensity from the previous year, as well as forward-looking exposure to risks from climate policies, and climate-related technological developments:

$$AISD_{f,b,t} = \alpha + \underbrace{\beta_1}_{>0}(risk)_{f,t} + \beta_2 \mathbf{S}_{b,j,t-1} + \underbrace{\beta_3}_{>0} \mathbf{S}_{b,j,t-1} \times (risk)_{f,t} + \tag{1}$$
$$\delta_f + \delta_{b,t} + \delta_{j,t} + \beta_f X_{f,t} + \beta_l X_{f,b,t} + \epsilon_{f,b,t}$$

where AISD is the All-in-spread-drawn charged to firm f by bank b in year t. $\delta_{b,t}$ controls for bank-year fixed effects, δ_f controls for borrower fixed effects, and $\delta_{j,t}$ controls for industry-year fixed effects. $S_{b,j,t-1}$ is the specialization indicator described in section 2.1.2 for bank b for industry j for the year before the lending contract was originated. $X_{f,b,t}$ and $X_{f,t}$ include loan-level controls and firm-level controls (as described in section 2.1) respectively.

If banks perceive the transition risk exposure variables as a reliable component of borrower's overall risk exposure, $\beta_1 > 0$ will be positive. If however, that is not the case, and only the specialized banks are differentially pricing-in transition risk for more exposed firms, β_3 will be > 0.

(2)

$$AISD_{f,b,t} = \alpha + \underbrace{\beta_1}_{>0}(risk)_{f,t} + \beta_2 \mathbf{S}_{b,j,t-1} + \underbrace{\beta_3}_{>0} \mathbf{S}_{b,j,t-1} \times (risk)_{f,t} + \beta_4 Shock_{t-i} + \beta_5 \mathbf{S}_{b,j,t-1} \times Shock_{t-i}$$
$$+ \beta_6 (risk)_{f,t} \times Shock_{t-i} + \underbrace{\beta_7}_{>0} \mathbf{S}_{b,j,t-1} \times (risk)_{f,t} \times Shock_{t-i} + \delta_f + \delta_{b,t} + \delta_{j,t} + \beta_f X_{f,t} + \beta_l X_{f,b,t} + \epsilon_{f,b,t}$$

where Shock_{t-i} is the mean value of oil supply news shock described in section 2.1.3 $i = 1, .., 4$ quarters before the loan contract was originated.

If there is an additional effect of shocks to oil markets increasing awareness about detrimental effects of potential disorderly transition risk realizations, especially by banks that are already specialized in the borrowers' industry, we will also observe β_7 to be positive.

Finally, to examine whether specialized banks price firms' transition risk exposure as reflected in their Scope 1 and Scope 2 emission intensity, as well as forward-looking exposure to risks from climate regulations, and climate-related technological developments from the previous year in periods after one quarter after a period of financial stress, I estimate the following regression:

(3)

$$AISD_{f,b,t} = \alpha + \underbrace{\beta_1}_{>0}(risk)_{f,t} + \beta_2 \mathbf{S}_{b,j,t-1} + \underbrace{\beta_3}_{>0} \mathbf{S}_{b,j,t-1} \times (risk)_{f,t} + \beta_4 Shock_{t-i} + \beta_5 \mathbf{S}_{b,j,t-1} \times Shock_{t-i} +$$
$$\beta_6 (risk)_{f,t} \times Shock_{t-i} + \underbrace{\beta_7}_{>0} \mathbf{S}_{b,j,t-1} \times (risk)_{f,t} \times Shock_{t-i} + \beta_8 FSI_{t-k} + \beta_9 (risk)_{f,t} \times FSI_{t-k} +$$
$$\beta_{10} \mathbf{S}_{b,j,t-1} \times FSI_{t-k} + \beta_{11} Shock_{t-i} \times FSI_{t-k} + \beta_{12} \mathbf{S}_{b,j,t-1} \times Shock_{t-i} \times FSI_{t-k} + \beta_{13} \mathbf{S}_{b,j,t-1} \times (risk)_{f,t} \times FSI_{t-k}$$
$$+ \beta_{14} (risk)_{f,t} \times Shock_{t-i} \times FSI_{t-k} + \underbrace{\beta_{15}}_{>0} (risk)_{f,t} \times \mathbf{S}_{b,j,t-1} \times FSI_{t-k} \times Shock_{t-i}$$
$$+ \delta_f + \delta_{b,t} + \delta_{j,t} + \beta_f X_{f,t} + \beta_l X_{f,b,t} + \epsilon_{f,b,t}$$

where FSI_{t-k} is the measure of overall financial stress one quarter before the contract was initiated.

I use the OFR Financial Stress Index for the U.S. (Bejarano 2023). The OFR FSI for the U.S. uses

26-33 financial market variables that are correlated with some form of financial stress. For the E.U., I use the Country-Level Index of Financial Stress (CLIFS) for the country that firm has headquarters in (Duprey et al. 2017). The CLIFS indicators include 6 market-based measures of financial stress across equity markets, credit markets and foreign exchange markets. Each of these indicators are able to identify period of high financial market stress with significant explanatory power.

2.3. Empirical Findings

2.3.1. Specialized banks and firm-level transition risk

Table 5 reports the estimation results for equation 1 with scope 1 and 2 GHG emission intensity (in million metric ton per USD) as a measure of exposure to transition risk without taking news shocks into account. I do not find any significant effects associated with higher emission intensity on the loan rates. Tables 6 and 7 report the estimation results for equation 1 with categorical variables such that:

- $\mathbf{I}[\text{relative frequency of negative tone words associated with climate regulations} > 0] = 1$
- $\mathbf{I}[\text{relative frequency of negative tone words associated with climate-related technological opportunities} > 0] = 1$

I find that on average across the entire sample, firms with negative regulatory exposure to climate policies are charged a higher loan rate by 12.70 bps relative to firms with no adverse climate regulatory exposure. I do not find any significant effects associated green technology-related exposure.

I split the sample between for E.U. firms and U.S. firms. There has been a consistent effort towards sustainability disclosure and decarbonization policies in the E.U. in the past decade. Along with the recent Sustainable Finance Disclosure Regulation (SFDR), the Non-Financial Reporting Directive (NFRD) adopted in 2014 required certain large companies to disclose non-financial information regarding environmental, social, and employee-related issues. This was further supplemented with the Guidelines on Reporting Climate-Related Information in 2019, and the E.U. Sustainable Taxonomy which provided detailed standardized guidelines on identifying sustainable economic activity.

In the same period, the U.S. climate policy suffered major upheavals. Between 2016 - 2022, major orders aimed at emission reduction were subjected to rollbacks or reviews. The administration under President Trump also withdrew from the Paris Climate Agreement. Starting 2021, under the Biden administration, U.S. re-joined the Paris Agreement, and the Inflation Reduction Act (2022) set out provisions to increase investment in decarbonization technologies such as renewable energy generation, clean transportation, and energy-efficient retrofits. However, the state of climate-related disclosures is still in a nascent stage, with the SEC finally adopting the Climate-Related Disclosure rules in 2024.

Keeping the above differences in mind, lenders and investors would face fewer frictions incorporating transition risk exposure in their financing decisions for E.U. firms, relative to U.S. firms. I do not find strong evidence supporting this hypothesis. While there is no significant association between high firm-level emission intensity and negative exposure to green technological developments, and interest rates charged, I find that on an average U.S. firms with negative regulatory exposure face higher lending rates (by 13.75 bps) whereas E.U. firms with negative regulatory exposure face lower lending rates (by 18 bps) relative to firms with non-negative regulatory exposure. However, I find a role for specialized banks in pricing negative regulatory exposure for E.U. firms. E.U. firms with negative climate-regulatory exposure face higher rates by 163.53 bps for loans made by banks specialized in the firms' industries. I do not find similar effects for U.S. firms[10].

2.3.2. Specialized banks and firm-level transition risk post-oil supply news shock

Tables 8, 11, and 14 present results for estimation of equation 2 with scope 1 and 2 GHG emission intensity (logarithmized) after taking into account oil supply news shocks lagged i quarters before the loan contract was originated. Across the entire sample, I find evidence for specialized banks charging firms with one percent higher emission intensity lower rates by 70.72 bps one quarter after a positive oil supply news shock. I do not find any effects of high emission intensity E.U. firms being charged higher rates by specialized banks after an oil supply news shock. However, I find evidence of lower rates being charged to U.S. firms with 1% higher emission intensity by specialized banks for a quarter after the oil supply news shock (Figure 2 - Panel A).

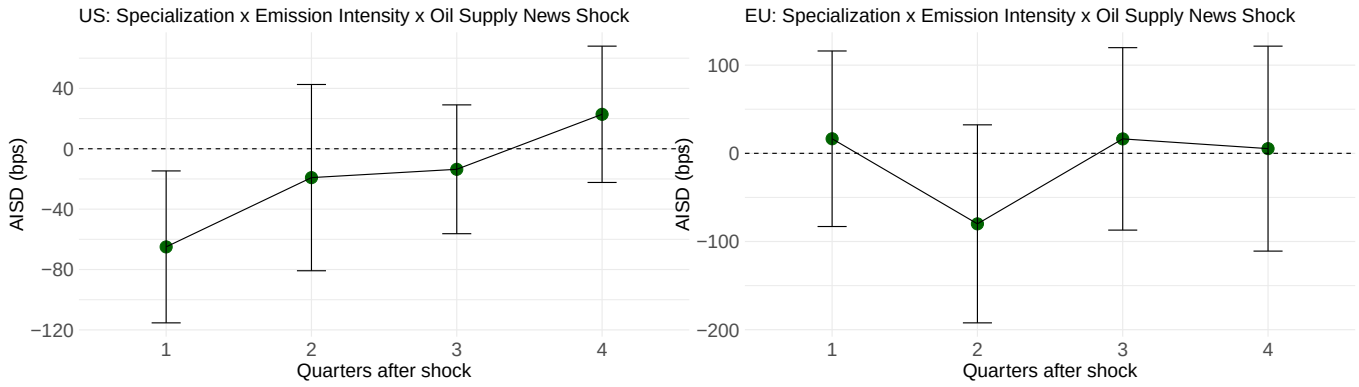

Tables 9, 12, and 15 present results for estimation of equation 2 with negative forward-looking climate-regulatory exposure after taking into account oil supply news shocks lagged i quarters before the loan contract was originated. I find no evidence for specialized banks charging firms with negative regulatory exposure higher rates after a positive oil supply news shock across the complete sample. Despite finding higher average rates being charged by specialized banks for negatively exposed E.U. firms, I find no differential effects after oil supply news shocks.charged higher rates by specialized banks after an oil supply news shock. Similarly, I find no significant effects on loan rates charged to U.S. firms negatively exposed to climate regulations by specialized banks (Figure 2 - Panel B).

Tables 10, 13, and 16 present results for estimation of equation 2 with negative forward-looking green-technology exposure after taking into account oil supply news shocks lagged i quarters before the loan contract was originated. Across the whole sample, I find no evidence for specialized banks charging negatively exposed firms higher lending rates after the oil supply news shock. However,

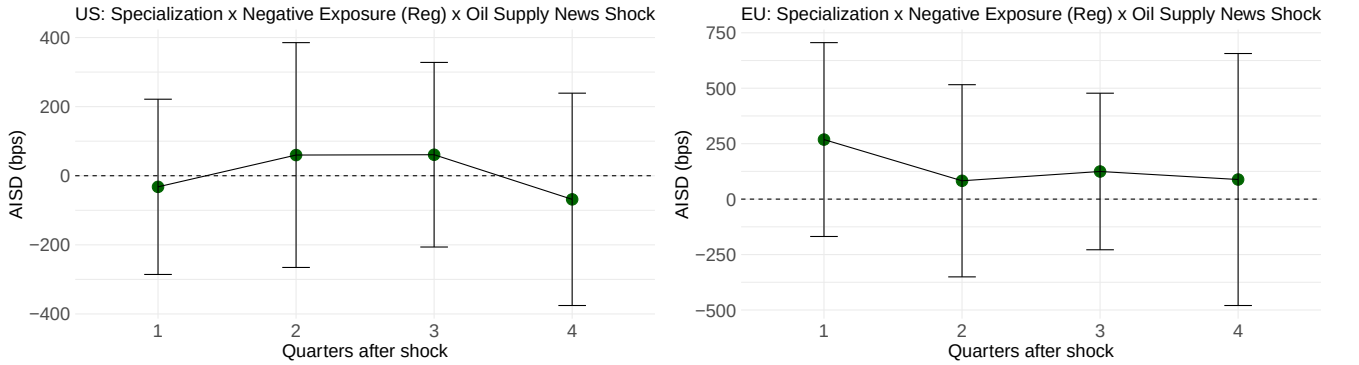

[10] I perform the empirical analysis with the measure of specialization calculated for two, three, and four years before the contract origination to account for the influence of any sporadic increase in lending to an industry a year before the loan contract origination. The magnitude and sign of the interaction variable stay consistent.

E.U. firms negatively exposed to green technologies are charged higher rates on average by 519.20 bps by specialized banks with a lag of three quarters after the oil supply news shock. On the other hand, I do not find any significant evidence that negatively exposed U.S. firms are charged higher rates by specialized banks after the oil supply news shock (Figure 2 - Panel C).

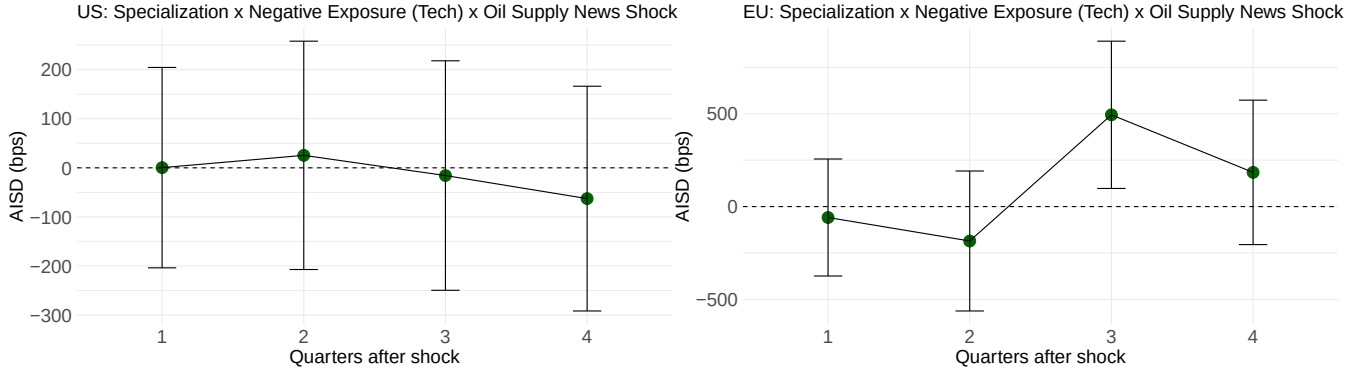

FIGURE 2. Effect of bank specialization on interest rates after oil supply news shock across different transition risk measures

A. Emission Intensity

B. Negative Exposure - Climate Regulations

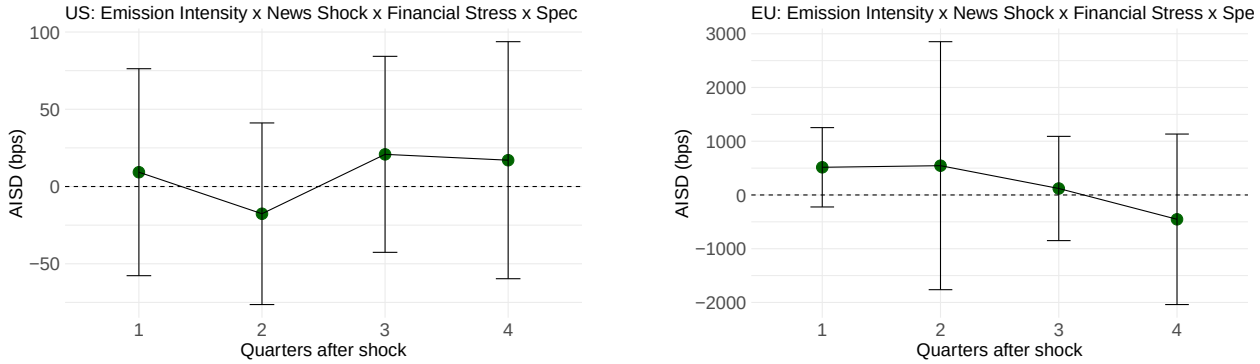

C. Negative Exposure - Green Technology

2.3.3. Specialized banks and firm-level transition risk post-oil supply news shock and financial stress

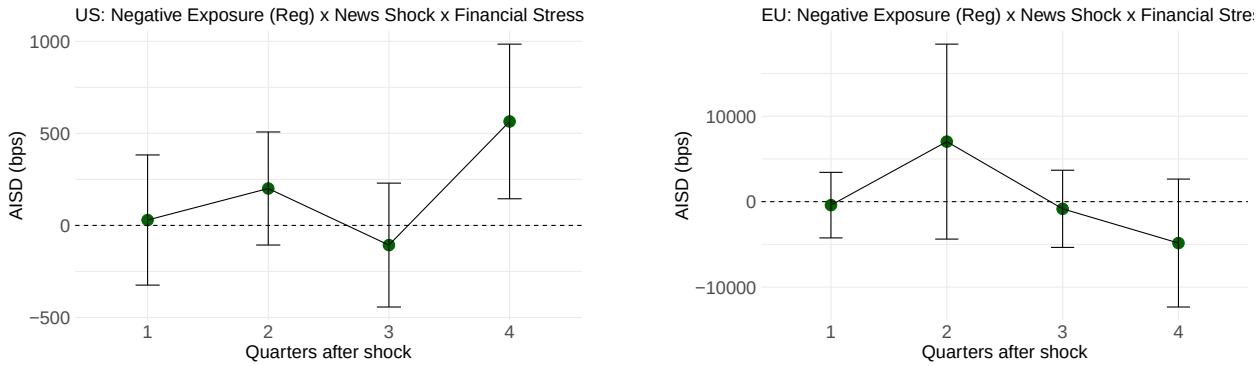

I present the estimation results from equation 3 for all the measures of firm-level transition risk after splitting the sample into U.S. and E.U. firms. For the U.S. I find high emission intensity as well as negative regulatory and green techonological exposure being charged relatively lower interest rates

on average for 2-4 quarters after an oil supply news shock for contracts initiated after a quarter of a period of high financial stress (Tables 23, 24, and 25). For E.U. firms, I find evidence for high emission intensity and negative exposure to green technologies being charged lower lending rates on average for contracts initiated after a quarter of a period of high financial stress, a quarter after an oil supply news shock (Tables 20, 21, and 22).

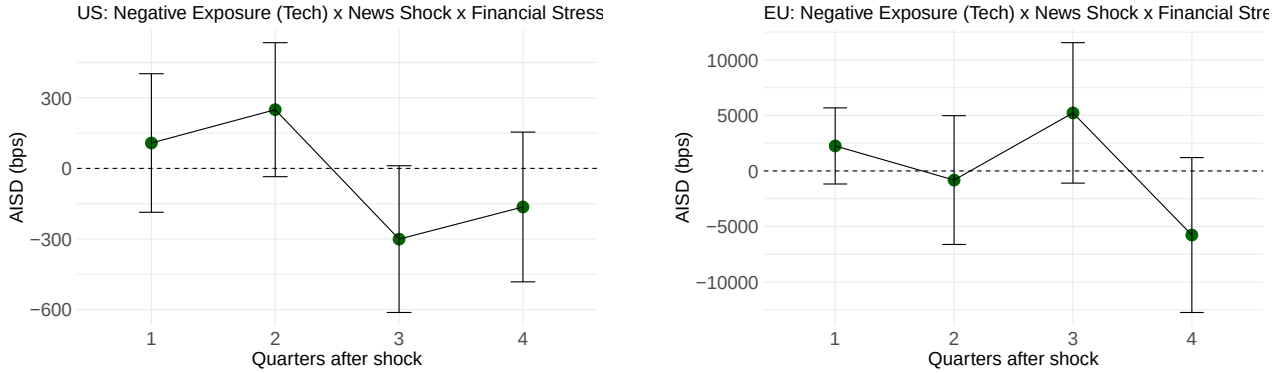

FIGURE 3. Effect of bank specialization on interest rates after oil supply news shock a quarter after increased financial stress across different transition risk measures

A. Emission Intensity

B. Negative Exposure - Climate Regulations

C. Negative Exposure - Green Technology

The empirical findings above show that periods of high financial stress can reduce the amount of relevant public information that even the specialized lenders incorporate in their lending decisions. This leads to an equilibrium where the effects of under-reaction are sharper and more exposed borrowers end up with more favorable lending rates than the less exposed borrowers. This has signif-

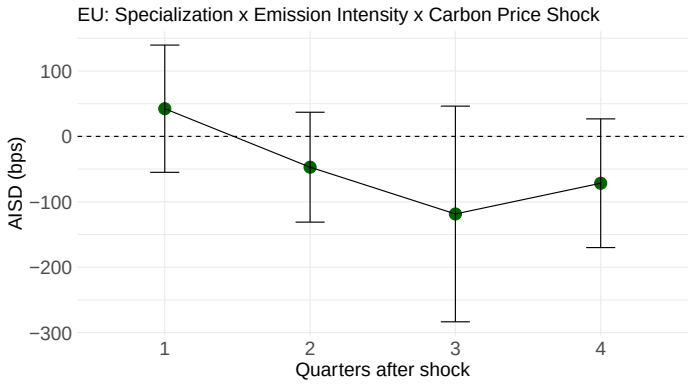

icant consequences for financing of decarbonization investments during periods of financial stress, with the cost of debt for more green and energy efficient firms not reflecting their lower exposure to transition risks.

2.3.4. Carbon price shocks

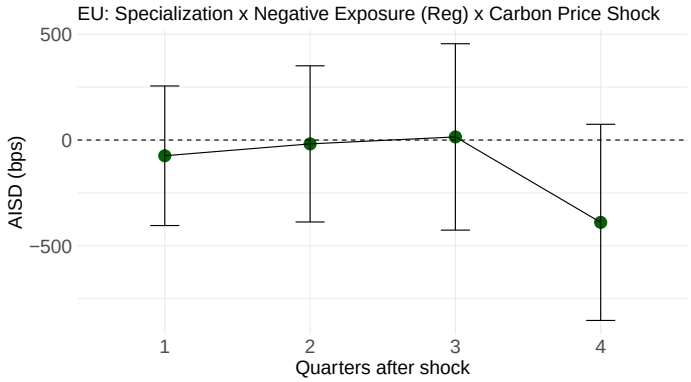

While the oil supply news shocks are relevant for energy prices, as well as for the firms adversely exposed to climate regulations, they do not specifically act as a transition risk shock. I focus the analysis in the previous section to shocks emerging from carbon pricing to understand bank pricing of firm-level exposure to transition risk after a transition risk shock. I use the carbon pricing shocks estimated in Känzig (2023). The shock series are constructed by identifying movements in the EU emission allowances (EUA) futures prices in narrow windows around carbon regulatory events. Since these shocks lead to a persistent fall in emissions (as well as a significant increase in energy prices), they can be a relevant proxy for shocks to the transition risk exposures of the firms. Since these shocks emerge from the European Emissions Trading Scheme (ETS), I incorporate them in equation 2 for loans made to E.U. firms.

Tables 17, 18, and 19 present results for estimation of equation 2 with risk measures after taking into account carbon pricing shocks lagged i quarters before the loan contract was originated. Across the whole sample, I find no evidence for specialized banks charging E.U. firms with higher emission intensity, negatively exposure to carbon regulations or negative exposure to green technologies higher lending rates after the carbon pricing shock (Figure 4).

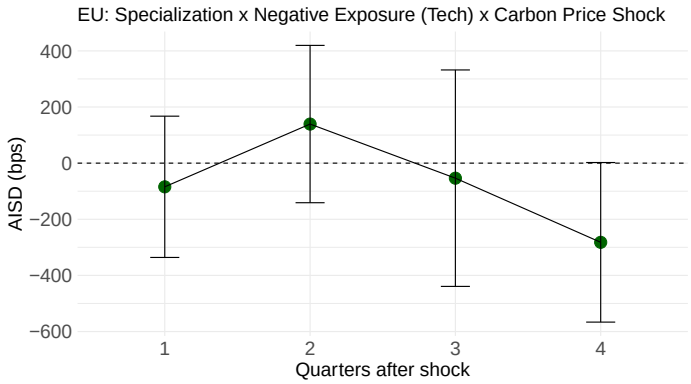

FIGURE 4. Effect of bank specialization on interest rates after carbon price shock across different transition risk measures

A. Emission Intensity

B. Negative Exposure - Climate Regulations

C. Negative Exposure - Green Technology

The results from the empirical analysis highlight two mechanisms that might explain the banking sector's role in pricing corporates' transition risk exposure:

a. Bank specialization in the borrower's industries provides industry-specific expertise to banks to understand and price regulatory aspects of transition risk exposure on average for more exposed firms.

b. Despite oil supply news shocks being relevant for energy prices and overall economic activity, even specialized banks either do not incorporate these shocks in lending decisions towards firms more exposed to transition risk, or respond with a significant lag. This response is sharper after

periods of high financial stress in the economy.

3. A model of imperfect screening and belief updates

To understand the role of bank specialization, and the under-reaction to observable oil supply news shocks that are relevant for emission-intensive firms, I incorporate costless public information in a model of competitive lending where one bank can acquire costly and imperfect private information about firms' transition risk exposure (Specialized) and the other bank faces prohibitively high information acquisition costs, and therefore, cannot acquire private information about its borrowers (Un-Specialized).

3.1. Borrowers

The environment consists of two types of entrepreneurs who belong to a type $j \in H, L$, where the L type borrowers are more exposed to climate transition risk than the H type. The mass of the entrepreneurs is publicly known, with the proportion of H entrepreneurs = λ. Both types of entrepreneur require an initial investment of one unit of capital and cannot use any other source of financing. As such, the model does not have an equity market[11].

The probability of success for a project also varies across entrepreneur types. Each entrepreneur has a successful project with a probability p_j; $j \in \{h, l\}$ and terminal cash-flow R, and an unsuccessful project with probability $1 - p_j$ and no terminal returns.

ASSUMPTION 1. *The probability of success for a H-type borrower is higher than that for a L-type borrower. Formally:* $p_h > p_l$

ASSUMPTION 2. *L-type borrowers would not be creditworthy if their type was observable, i.e.* $p_l R < 1 < p_h R$

ASSUMPTION 3. *The average borrower is creditworthy under imperfect information such that* $\bar{p}R > 1$; *where* $\bar{p} = \lambda p_h + (1 - \lambda) p_l$

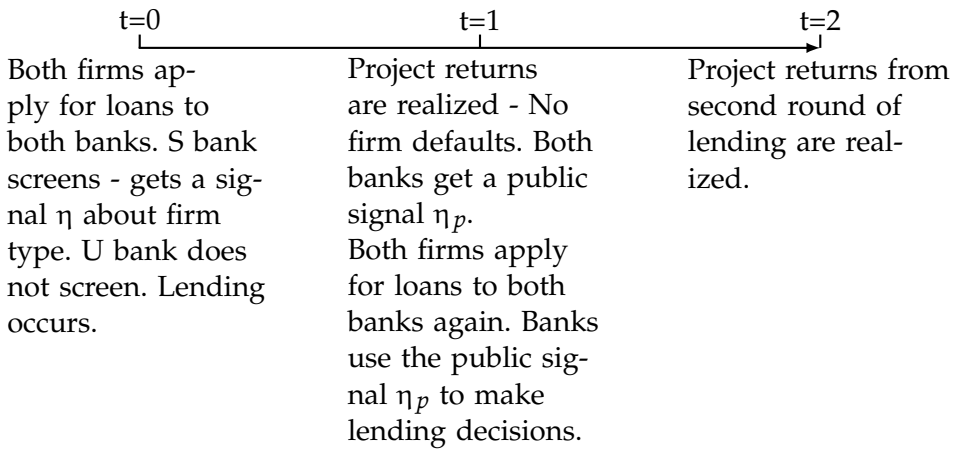

3.2. Banks

There are two banks, "S" (specialized) and "U" (unspecialized), which compete for firms in the market for loans. The former conducts a screening process for the borrowers, and the latter does not. The quality of information acquired by the S bank is endogenous. Banks do not observe if the entrepreneur is an H type. While the screening decision of the S bank is exogenously determined, the

[11] The debt-equity financing decision can also be affected when lending is affected by climate risk beliefs. This model does not focus on that component.

amount of screening conducted by the S bank is endogenous. To understand the effects of information on prices, I set the lending decisions to be unsecured. Every equilibrium lending decision comprises an equilibrium interest rate r.

FIGURE 5. Timeline of the lending process

Private signal from screening for the S bank: The S bank conducts a screening process for a borrower's first-time application, which yields a signal $\eta \in \{l, h\}$. The results of the screening process cannot be observed by the U bank, and hence there are no information spillovers. In the context of climate risk, screening could include assessment of the firm's production history, GHG emissions, and investments in energy efficiency. The signal is informative but imperfect, i.e., it reveals the correct type of the borrower with probability ϕ (precision of the signal):

$$Pr(\eta = h|H) = Pr(\eta = l|L) = \phi \geq \frac{1}{2}$$

$$Pr(\eta = h|L) = Pr(\eta = l|H) = 1 - \phi$$

There is an increasing and convex cost to screening: $C(\phi) = \frac{(\phi - 0.5)^2}{2}$, which implies that the optimal level of screening will depend on the parameters of the model. Thus, this becomes a problem of information acquisition in a perfectly competitive market.

Since there are no information spillovers from screening, the screening bank has an informational advantage over the non-screening banks. In the second round of lending starting in period $t = 1$, the informed bank can choose not to screen again since it already has an informative signal about the climate-risk related creditworthiness of the borrower. I assume that after the returns from projects are realized in $t = 1$, none of the firms has defaulted[12].

Public signal: An informative public signal (η_p) about transition risk appears in period $t = 1$,

[12]This is a simplifying assumption to abstract from the information generated by the distinction between defaulting and non-defaulting firms.

which both banks observe. This signal could be a geopolitical event that positively shocks energy prices,an adverse weather event that triggers discussions about policy solutions to climate change and global warming, or the release of new information about the development of a new climate-friendly technology. This signal is imperfect but informative, independent of the precision of the signal from screening, and costless to observe.

$$Pr(\eta_p = h_p|H) = Pr(\eta_p = l_p|L) = \phi_p \geq \frac{1}{2}$$

$$Pr(\eta_p = h_p|L) = Pr(\eta_p = l_p|H) = 1 - \phi_p$$

LEMMA 1. *If the types of the borrowers could be perfectly observed, then under the setup of the model, the L type borrower would not receive a loan from either of the banks. Both banks would compete for the H type borrower, and with Bertrand-like repeated undercutting, both banks in equilibrium would charge the same interest rate r to the H type, which would be equal to their break-even interest rate:*

$$p_h\bar{r} - 1 = 0 \Rightarrow \bar{r} = \frac{1}{p_h}$$

The effect of imperfect information can be easily surmised from the above information - as the known probability with which a borrower can be deemed H or L decreases, the equilibrium interest rate increases, driving the H entrepreneurs out of the borrower pool. This is the standard adverse selection result. Under perfect competition and with no bank having an informational advantage over the other, the average probability of success of a borrower would be $\bar{p}$ as defined above, and the equilibrium interest rate would be $\bar{r} = \frac{1}{\bar{p}}$. Each bank would make zero profit by bidding this interest rate.

LEMMA 2. *After observing the signals from screening, the S bank updates its beliefs about the borrowers. The posterior probabilities for each type are:*

$$P(type = H|\eta = h) = \frac{\lambda\phi}{\phi\lambda + (1-\phi)(1-\lambda)} = H$$

$$P(type = L|\eta = h) = \frac{(1-\lambda)(1-\phi)}{\phi\lambda + (1-\phi)(1-\lambda)} = 1 - H$$

$$P(type = L|\eta = l) = \frac{\phi(1-\lambda)}{\phi(1-\lambda) + (1-\phi)\lambda} = L$$

$$P(type = H|\eta = l) = \frac{\lambda(1-\phi)}{\phi(1-\lambda) + (1-\phi)\lambda} = 1 - L$$

The corresponding probabilities of success for a project upon observing the signal η *are:*

$$p(h) = P(Returns = R|\eta = h) = Hp_h + (1-H)p_l$$

$$p(l) = P(Returns = R|\eta = l) = (1-L)p_h + Lp_l$$

Upon observing the public signal $\eta_p \in \{l_p, h_p\}$, both banks update the probabilities of the borrower being successful. However, there is the possibility of inertia in learning about transition risks by banks[13]. Consistent with (Epstein et al. 2010) and (Cripps 2018), the posterior success probabilities are a linear combination of the beliefs the banks had in period $t = 1$ and the Bayesian posterior after observing the public signal η_p. This inertia is captured by the parameter $\mu \in [0, 1]$, such that $\mu = 0$ is consistent with strict Bayesian updating, and $\mu = 1$ corresponds to no update.

LEMMA 3. *The success probabilities used by the S bank to calculate the breakeven interest rates for the different groups of borrowers are as follows after observing the public signal* η_p *:*

- $p(hh_p) = \mu p(h) + (1-\mu)\left[\frac{\lambda\phi\phi_p p_h + (1-\lambda)(1-\phi)(1-\phi_p)p_l}{\lambda\phi\phi_p + (1-\lambda)(1-\phi)(1-\phi_p)}\right]$
- $p(lh_p) = \mu p(l) + (1-\mu)\left[\frac{\lambda(1-\phi)\phi_p p_h + (1-\lambda)\phi(1-\phi_p)p_l}{\lambda(1-\phi)\phi_p + (1-\lambda)\phi(1-\phi_p)}\right]$
- $p(hl_p) = \mu p(h) + (1-\mu)\left[\frac{\lambda\phi(1-\phi_p)p_h + (1-\lambda)(1-\phi)\phi_p p_l}{\lambda\phi(1-\phi_p) + (1-\lambda)(1-\phi)\phi_p}\right]$
- $p(ll_p) = \mu p(l) + (1-\mu)\left[\frac{\lambda(1-\phi)(1-\phi_p)p_h + (1-\lambda)\phi\phi_p p_l}{\lambda(1-\phi)(1-\phi_p) + (1-\lambda)\phi\phi_p}\right]$

The U bank does not conduct screening but observes the public signal, on the basis of which it updates its beliefs about the borrowers' types, similar to the update process of the S bank:

- $p(h_p) = P(Returns = R|\eta = h_p) = \mu[\lambda p_h + (1-\lambda)p_l] + (1-\mu)\left[\frac{\lambda\phi_p p_h + (1-\lambda)(1-\phi_p)p_l}{\lambda\phi_p + (1-\lambda)(1-\phi_p)}\right]$
- $p(l_p) = P(Returns = R|\eta = l_p) = \mu[\lambda p_h + (1-\lambda)p_l] + (1-\mu)\left[\frac{\lambda(1-\phi_p)p_h + (1-\lambda)\phi_p p_l}{(1-\lambda)\phi_p + \lambda(1-\phi_p)}\right]$

3.2.1. Expected profits after observing the public signal

ASSUMPTION 4. *The informativeness level of* ϕ *is such that the borrower with signals* l, l_p *is not creditworthy, i.e.,* $p(ll_p(\bar{\phi}))R < 1$

Since the S bank observes two distinct signals in periods 0 and 1, it can distinguish between four different types of borrowers based on the signals, and the respective ex-ante profits are as follows[14]:

$$\pi_S^{hh_p} = (p(hh_p)r - 1)(1 - F_U^{h_p}(r))$$

[13] In Appendix C, I provide empirical evidence for how beliefs about exposure to damage from climate change among individuals might update after witnessing a major state-level disaster while remaining strongly anchored to their beliefs in the past.

[14] Since both η and η_p are informative, $p(hh_p) > p(h_p) > p(hl_p) and p(hl_p) > p(l_p) > p(ll_p)$

$$\pi_S^{hl_p} = (p(hl_p)r - 1)(1 - F_U^{l_p}(r))$$

$$\pi_S^{lh_p} = (p(lh_p)r - 1)(1 - F_U^{h_p}(r))$$

$$\pi_S^{ll_p} = (p(ll_p)r - 1)(1 - F_U^{l_p}(r))$$

where $F_U^j(r)$ is the cumulative density function for the U-bank's interest rate after observing the public signal j.

Similarly, the expected profits for the U bank, given that it cannot observe the signal from screening by the S-bank, are:

$$\pi_U^{h_p} = Pr(\eta = h|\eta_p = h_p)(p(hh_p)r - 1)(1 - F_S^{hh_p}(r)) + Pr(\eta = l|\eta_p = h_p)(p(lh_p)r - 1)(1 - F_S^{lh_p}(r))$$

$$\pi_U^{l_p} = Pr(\eta = h|\eta_p = l_p)(p(hl_p)r - 1)(1 - F_S^{hl_p}(r)) + Pr(\eta = l|\eta_p = l_p)(p(ll_p)r - 1)(1 - F_S^{ll_p}(r))$$

where $F_S^j(r)$ are the S bank's interest rate bidding distribution for $j = hh_p, lh_p, hl_p, ll_p$

Consistent with the standard result for competition under asymmetric information, the U bank does not make positive expected profits with simultaneous bidding, since it does not have any informational advantage over the S bank, even after observing the public signal (Engelbrecht-Wiggans et al. 1983). Thus, the U bank will break even in equilibrium.

Proposition 1: *The competition between the S bank and the U bank has a mixed strategy equilibrium for borrowers facing both types of public signals. The common support for interest rates for borrowers facing* $\eta_p = h_p$ *is* $[\bar{r}_{h_p}, \bar{r}_{lh_p})$*, and the common support for borrowers facing* $\eta_p = l_p$ *is* $[\bar{r}_{l_p}, R)$*. The S bank does not bid for borrowers facing the signals* (l, l_p)

Proof: For borrowers facing public signal $\eta_p = h_p$, the breakeven interest rate for the U bank is $r_U^{h_p} = \bar{r}_{h_p} = \frac{1}{p(h_p)}$. At this interest rate, the U bank is able to capture the h_p borrowers for sure. The S bank has an informational advantage and can distinguish between hh_p and lh_p borrowers. Charging $\bar{r}_{h_p}$ to the hh_p borrowers, the S bank makes positive profits since $\bar{r}_{h_p} p(hh_p) - 1 = \frac{p(hh_p)}{p(h_p)} - 1 > 0$, and hence, it has no reason to charge below this interest rate. However, for the lh_p borrower, $\bar{r}_{lh_p} = \frac{1}{p(lh_p)} > \bar{r}_{h_p}$. With repeated undercutting, the S-bank charges $\bar{r}_{lh_p}$ in a pure strategy and makes zero profits.

By the definition of $\bar{\phi}$, the S bank does not lend to the ll_p borrower. The U bank captures any l_p borrower at the breakeven interest rate $\bar{r}_{l_p} = \frac{1}{p(l_p)}$, and to maintain the borrower's participation constraint, it will not charge any borrower more than R. Since $\bar{r}_{hl_p} = \frac{1}{p(hl_p)} < \bar{r}_{l_p}$, the S-bank will make positive profits by charging $\bar{r}_{l_p}$. So, the lower bound for the support for interest rate charged to the

l_p borrower is $\bar{r}_{l_p}$[15].

Since $\bar{r}_{h_p} < \bar{r}_{lh_p} < \bar{r}_{lh_p} \forall \quad \phi_p \geq \frac{1}{2}$, the distribution of the expected interest rate for a borrower facing a public signal h_p lies to the left of the distribution of the expected interest rate for a borrower facing a public signal l_p, such that there is no overlap between the two distributions. This implies that the expected interest rate paid by a borrower facing h, h_p signals will be lower than that for any borrower facing a public signal l_p.

LEMMA 4. *The cumulative distribution functions over which the S bank can choose interest rates after observing the public signal* $\eta_p \in \{h_p, l_p\}$ *are:*

$$F_S^{hh_p}(r) = 1 - \frac{1 - p(lh_p)r}{p(hh_p)r - 1} \cdot \frac{Pr(\eta = l|\eta_p = h_p)}{P(\eta = h|\eta_p = h_p)}$$
$$F_S^{hl_p}(r) = 1 - \frac{1 - p(ll_p)r}{p(hl_p)r - 1} \cdot \frac{Pr(\eta = l|\eta_p = l_p)}{Pr(\eta = h|\eta_p = l_p)}$$

The cumulative distribution functions over which the U bank can choose interest rates after observing the public signal $\eta_p \in \{h_p, l_p\}$ *are:*

$$F_U^{h_p}(r) = 1 - \frac{p(hh_p)\bar{r}_{h_p} - 1}{p(hh_p)r - 1}$$
$$F_U^{l_p}(r) = 1 - \frac{p(hl_p)\bar{r}_{l_p} - 1}{p(hl_p)r - 1}$$

Proof: Equilibrium profits for both banks must be the same for any r in the common support derived in Proposition 1 for the banks to not deviate. Consequently, using the profit functions conditional on public signals defined above:

- From the S bank's expected profits conditional on observing the public signal h_p for a borrower:

$$\pi_S(\eta_p = h_p) = (p(hh_p)\bar{r}_{h_p} - 1) = (p(hh_p)r - 1)(1 - F_U^{h_p}(r))^{16}$$
$$\Rightarrow F_U^{h_p}(r) = 1 - \frac{p(hh_p)\bar{r}_{h_p} - 1}{p(hh_p)r - 1}$$

- From the U bank's expected profits conditional on observing the public signal h_p for a borrower:

$$\pi_U(\eta_p = h_p) = P(\eta = h|\eta_p = h_p)(p(hh_p)r - 1)(1 - F_S^{hh_p}(r)) + Pr(\eta = l|\eta_p = h_p)(p(lh_p)r - 1) = 0^{17}$$
$$\Rightarrow F_S^{hh_p}(r) = 1 - \frac{1 - p(lh_p)r}{p(hh_p)r - 1} \cdot \frac{Pr(\eta = l|\eta_p = h_p)}{P(\eta = h|\eta_p = h_p)}$$

[15] A separate case for when the screening is sufficiently informative is when the S bank lends to the ll_p borrower. Results for this case are currently in progress

- From the S bank's expected profits conditional on observing the public signal l_p for a borrower:

$$\pi_S(\eta_p = l_p) = (p(hl_p)\bar{r}_{l_p} - 1) = (p(hl_p)r - 1)(1 - F_U^{l_p}(r))^{18}$$
$$\Rightarrow F_U^{l_p}(r) = 1 - \frac{p(hl_p)\bar{r}_{l_p} - 1}{p(hl_p)r - 1}$$

- From the U bank's expected profits conditional on observing the public signal l_p for a borrower:

$$\pi_U(\eta_p = l_p) = P(\eta = h|\eta_p = l_p)(p(hl_p)r - 1)(1 - F_I^{hl_p}(r)) + Pr(\eta = l|\eta_p = l_p)(p(ll_p)r - 1) = 0^{19}$$
$$\Rightarrow F_S^{hl_p}(r) = 1 - \frac{1 - p(ll_p)r}{p(hl_p)r - 1} \cdot \frac{Pr(\eta = l|\eta_p = l_p)}{Pr(\eta = h|\eta_p = l_p)}$$

3.3. Expected interest rates

The interest rate paid by a borrower on a loan will be the $min\{r_S, r_U\}$, where r_S is the interest rate offered by the screening bank and r_U is the interest rate offered by the non-screening bank. In order to compare the effect of belief updates on the interest rates, I calculate the expected interest rates for borrower group j where $j \in \{hh_p, lh_p, lh_p, ll_p\}$, i.e.

$$E\left[min\{r_S^j, r_U^j\}\right] = \int_{lower_bound}^{upper_bound} rdF(r); \text{where} F(r) = F_S^j(r) + F_U^j(r) - F_S^j(r)F_U^j(r)$$

The distribution function for the minimum interest rate is derived as above since $F_S(r)$ and $F_U(r)$ are independent as both banks bid simultaneously. The distribution function for expected interest rates for all the groups are:

- $F^{hh_p}(r) = F_S^{hh_p}(r) + F_U^{h_p}(r) - F_S^{hh_p}(r)F_U^{h_p}(r) \quad \text{where} \quad r \in [\bar{r}_{h_p}, \bar{r}_{lh_p})$
- $F^{lh_p}(r) = F_U^{h_p}(r) \quad \text{where} \quad r \in [\bar{r}_{h_p}, \bar{r}_{lh_p})$
- $F^{hl_p}(r) = F_S^{hl_p}(r) + F_U^{l_p}(r) - F_S^{hl_p}(r)F_U^{l_p}(r) \quad \text{where} \quad r \in [\bar{r}_{l_p}, R)$
- $F^{ll_p}(r) = F_U^{l_p}(r) \quad \text{where} \quad r \in [\bar{r}_{l_p}, R)$

Proposition 2: *Conditional on any private signal* η *from the screening process in the first period, the expected interest rate will be higher for borrowers who receive a low public signal in the second period, i.e.* $E\left[r_{ll_p}\right] > E\left[r_{lh_p}\right]$ *and* $E\left[r_{hl_p}\right] > E\left[r_{hh_p}\right]$. *The interest rate differentials at a given level of* ϕ *and* ϕ_p *decrease as the underreaction (i.e.,* μ*) increases.*

Proof: Given the structure of the distribution functions for interest rates for different borrower groups, for borrowers who receive a low signal from private screening conducted by the S bank

in the first period:

$$F_{lh_p}(r) = 1 - \left[\frac{(p(hh_p)\bar{r}_{h_p} - 1)}{(p(hh_p)r - 1)}\right]$$

$$F_{ll_p}(r) = 1 - \left[\frac{(p(hl_p)\bar{r}_{l_p} - 1)}{(p(hl_p)r - 1)}\right]$$

$$\Rightarrow E\left[r_{ll_p}\right] - E\left[r_{lh_p}\right] = \int_{\bar{r}_{l_p}}^{R} r dF_{ll_p}(r) - \int_{\bar{r}_{h_p}}^{\bar{r}_{lh_p}} r dF_{lh_p}(r)$$

$$= \int_{\bar{r}_{l_p}}^{R} \frac{p(hl_p)\bar{r}_{l_p} - 1)p_{hl_p}}{(p(hl_p)r - 1)^2} rdr - \int_{\bar{r}_{h_p}}^{(\bar{r}_{lh_p}} \frac{(p(hh_p)\bar{r}_{h_p} - 1)p_{hh_p}}{(p(hh_p)r - 1)^2} rdr$$

which is $> 0 \quad \forall \quad \phi, \phi_p \geq \frac{1}{2} \quad$ and $\quad \mu \in [0, 1]$

Similarly, for borrowers who received a high signal from private screening conducted by the S bank in the first period:

$$F_{hh_p}(r) = 1 - \left[\frac{(1 - p(lh_p)r)(p(hh_p)\bar{r}_{h_p} - 1)}{(p(hh_p)r - 1)^2}\right]\left[\frac{Pr(\eta = l|\eta_p = h_p)}{Pr(\eta = h|\eta_p = h_p)}\right]$$

$$F_{hl_p}(r) = 1 - \left[\frac{(1 - p(ll_p)r)(p(hl_p)\bar{r}_{l_p} - 1)}{(p(hl_p)r - 1)^2}\right]\left[\frac{Pr(\eta = l|\eta_p = l_p)}{Pr(\eta = h|\eta_p = l_p)}\right]$$

$$\Rightarrow E\left[r_{hl_p}\right] - E\left[r_{hh_p}\right] = \int_{\bar{r}_{l_p}}^{R} r dF_{hl_p}(r) - \int_{\bar{r}_{h_p}}^{\bar{r}_{lh_p}} r dF_{lh_p}(r)$$

which is $> 0 \quad \forall \quad \phi, \phi_p \geq \frac{1}{2} \quad$ and $\quad \mu \in [0, 1]$

The detailed proof of Proposition 2 is presented in Appendix B. The relationship between interest rate differentials and μ varies with different levels of informativeness for the private screening signal ϕ. When screening is highly informative, ignoring a highly informative public signal would imply that interest rate differentials are in favor of borrowers, with the public signal pointing to l_p (Figure 6). Moreover, with increasing underreaction (or increasing μ), the decline in interest rate differentials is steeper under an increase in the informativeness of the public signals, since the information loss due to the underreaction is higher (Figure 7).

FIGURE 6. Expected interest rate differential (High informativeness of screening)

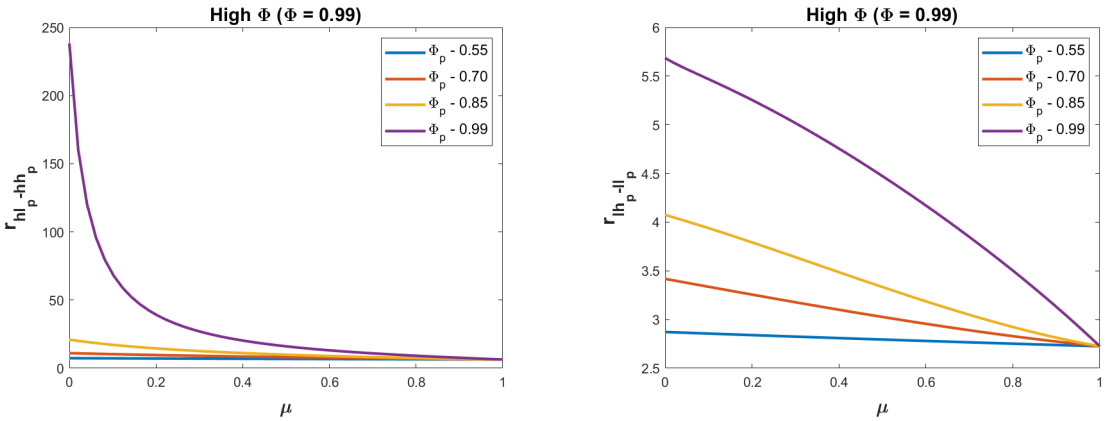

FIGURE 7. Expected interest rate differential (Medium informativeness of screening)

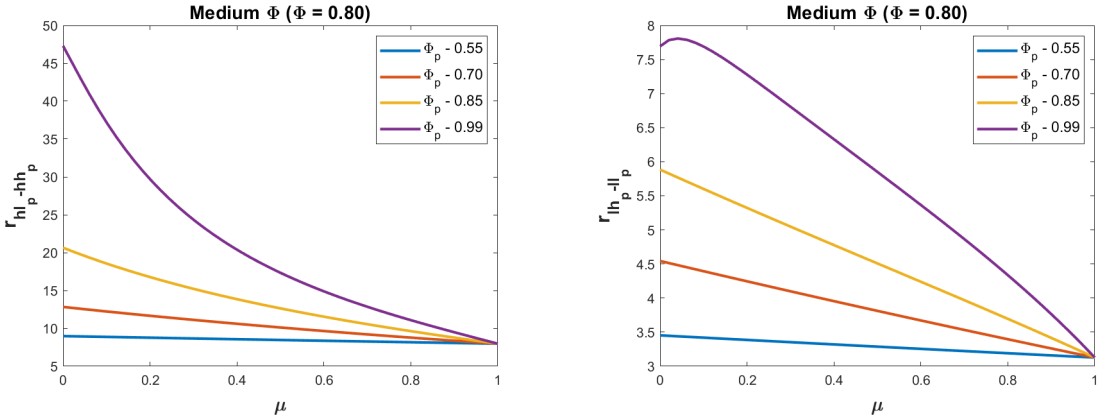

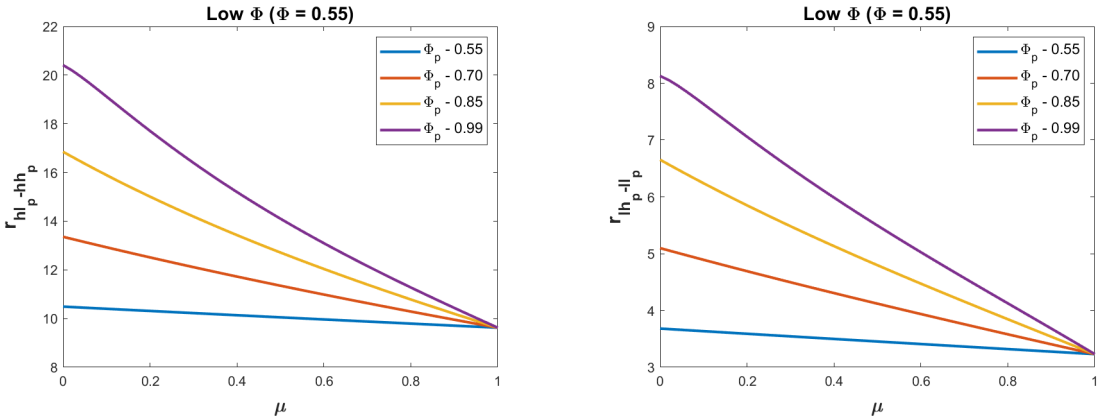

FIGURE 8. Expected interest rate differential (Low informativeness of screening)

For $\lambda = 0.4$, $p_h = 0.3$, $p_l = 0.1$

Proposition 2 provides a mechanism to understand the emerging empirical literature on the pricing of firms' transition risk exposure in lending contracts. An informative public signal about transition risk, such as a carbon policy announcement, or improvements in renewable energy technology, provides an additional tool to (partially) resolve imperfect information in a perfectly competitive banking environment. These predictions are consistent with the empirical findings in Section 2.

3.4. Expected second-period profits for the screening bank

The S bank makes zero profits on borrowers facing signals (l, h_p) and does not bid for borrowers facing signals (l, l_p). Substituting for the cumulative distribution functions for the interest rates offered

by the uninformed bank, the expected profit function for the specialized bank is:

$$\pi_S = P(\eta = h|\eta_p = h_p)(p(hh_p)\bar{r}_{h_p} - 1) + P(\eta = h|\eta_p = l_p)(p(hl_p)\bar{r}_{l_p} - 1) - \frac{(\phi - 0.5)^2}{2}$$
$$= \left[\lambda\phi\phi_p + (1-\lambda)(1-\phi)(1-\phi_p)\right] \cdot \left[\frac{\lambda\phi\phi_p p_h + (1-\lambda)(1-\phi)(1-\phi_p)p_l}{\lambda\phi\phi_p + (1-\lambda)(1-\phi)(1-\phi_p)}\bar{r}_{h_p} - 1\right]$$
$$+ \left[\lambda(1-\phi)\phi_p + (1-\lambda)\phi(1-\phi_p)\right] \cdot \left[\frac{\lambda\phi(1-\phi_p)p_h + (1-\lambda)(1-\phi)\phi_p p_l}{\lambda\phi(1-\phi_p) + (1-\lambda)(1-\phi)\phi_p}\bar{r}_{l_p} - 1\right] - \frac{(\phi - 0.5)^2}{2}$$

The specialized bank's resultant profit maximization function is:

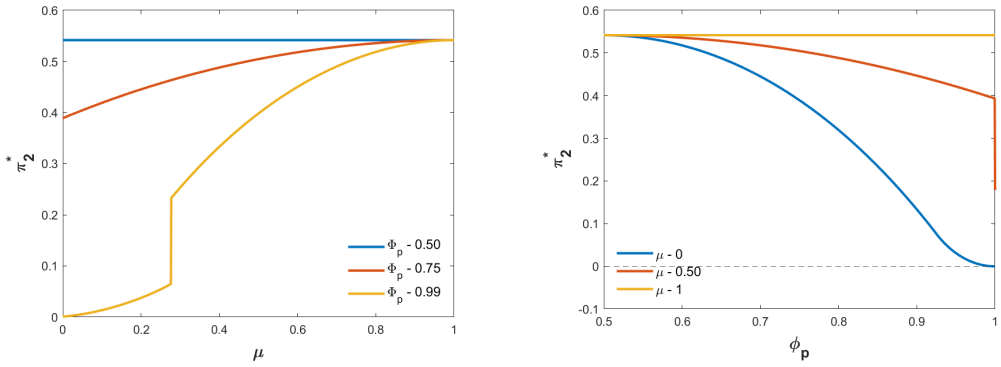

$$\max_{\phi} \quad \pi_S = P(\eta = h|\eta_p = h_p)(p(hh_p)\bar{r}_{h_p} - 1) + P(\eta = h|\eta_p = l_p)(p(hl_p)\bar{r}_{l_p} - 1) - \frac{(\phi - 0.5)^2}{2}$$
$$\text{s.t.} \quad 0.5 \le \phi \le 1$$
$$0.5 \le \phi_p \le 1$$

The second period gross profits (and hence the informational advantage) of the screening bank are not linearly increasing in ϕ and depend on the precision of the public signal ϕ_p and the level of underreaction μ. The maximum profits of the informed bank increase as μ increases because the uninformed bank is no longer taking advantage of a costless and informative signal, giving the informed bank an informational advantage. Keeping all other parameters constant, maximum profits decrease with ϕ_p.

Moreover, this decrease is sharper when μ is smaller or when banks' updates are Bayesian (Figure 9). This could again be attributed to informational advantage. With more informative public signals, the uninformed bank can update its beliefs about the success probabilities of the borrower – which, in a perfectly competitive market, would lower the equilibrium interest rates and thereby lower profits. The update in success probabilities is greater when the banks are Bayesian, and thus the competition resulting from the public signal would be stronger.

FIGURE 9. Optimal profits for the screening bank

A. With ϕ_p B. With μ

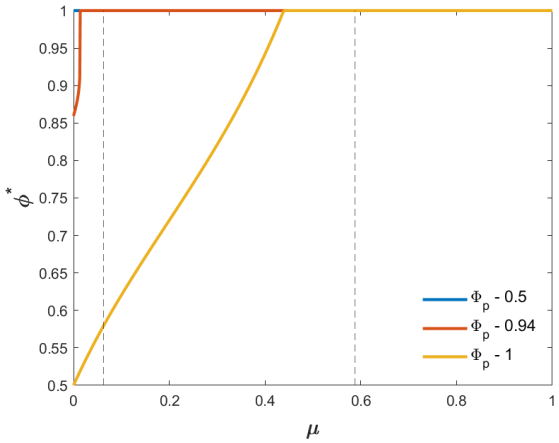

For $\lambda = 0.4$, $p_h = 0.3$, $p_l = 0.1$

3.5. Optimal private information acquisition (ϕ^*)

Proposition 3: *The informed lender facing* λ, p_h, p_l *optimally chooses* ϕ^* *by maximizing* π_2^* *such that (i)* $\forall\ \phi_p\ \exists\ \bar{\mu} \in [0,1]$ *for which* $\phi^*(\phi_p, \mu > \bar{\mu}) = 1$ *and (ii)* $\forall\ \phi_p > 0.5$, ϕ^* *increases non-monotically with* $\mu \in [0, \bar{\mu}]$. The profit-maximizing level of information acquisition by the informed bank ϕ^* nonlinearly increases with μ given sufficiently high-quality public information ϕ (Figure 10). This result is aligned with the literature on the crowding-out effects of public information, specifically, with the theoretical work showing that more informative public signals crowd out the acquisition of private information (Colombo et al. 2014). However, the underreaction parameter adds another dimension to this analysis in this model of convex information costs and nonlinear profits. While private information acquisition is lower for more informative public signals, this effect only holds true if the lender is sufficiently Bayesian. After crossing a certain threshold of μ, the lenders' underreaction to public information is sufficient for the informed lender to depend upon private information acquisition to achieve a profit-maximizing informational advantage over the uninformed lender.

FIGURE 10. Optimal level of screening

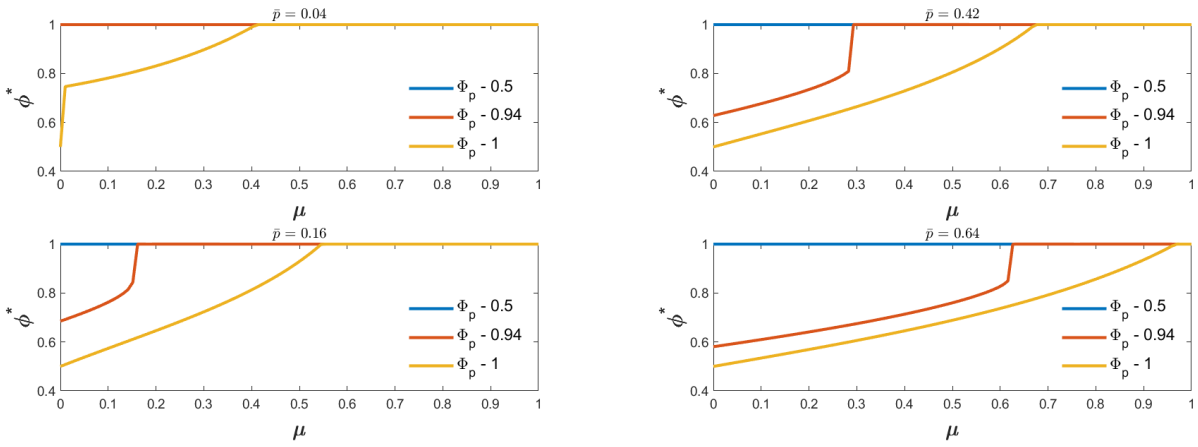

For $\lambda = 0.4$, $p_h = 0.3$, $p_l = 0.1$

3.6. Private information acquisition and average project quality

REMARK 1. *The crowding-out effect of public information on private information also varies with the average borrower quality in the economy (Figure 11). As the probability of success for the average borrower ($\bar{p} = \lambda p_h + (1-\lambda) p_l$) increases, given high levels of informativeness for public information, private information acquisition increases if the lenders are sufficiently Bayesian (i.e., $\mu < \bar{\mu}$). This implies that the lender depends more on private information given higher average credit risk in the economy.*

This "state dependence" of private information acquisition is further affected by the underreaction of the lenders. With the greater average success probability of a borrower, the threshold of underreaction after which the lender depends only on private information acquisition (despite more precise public information) increases, implying a greater incorporation of public information into the optimal decision for underreaction below a threshold $\bar{\mu}$.

FIGURE 11. Optimal private information acquisition with average borrower quality

Consequently, there is an impact on interest rate differentials. States of poor average borrower

quality reduce the threshold of underreaction below which the lender relies on both public and private information. As the average borrower quality increases, the crowding-out effects of public information on private information become apparent, in that the screening lender's incentive to acquire private information is reduced. Under a certain threshold of underreaction, this crowding-out effect steadily declines as underreaction increases, implying that the level of private information acquired increases to approach perfect quality. The interest rate differential between more and less exposed borrowers increases even with increasing underreaction due to increasing private information.

Beyond that threshold, the interest rate differential again declines with underreaction (Figures 12 and 13). This implies that for low $\bar{p}$, even small levels of underreaction to an informative public signal can result in a lower interest rate differential between more and less exposed borrowers. This mechanism is especially relevant for understanding the dynamics of bank financing for green technologies in times of higher average credit or liquidity risk in the economy.

FIGURE 12. Interest rate differential and average borrower quality (for borrowers with $\eta = h$)

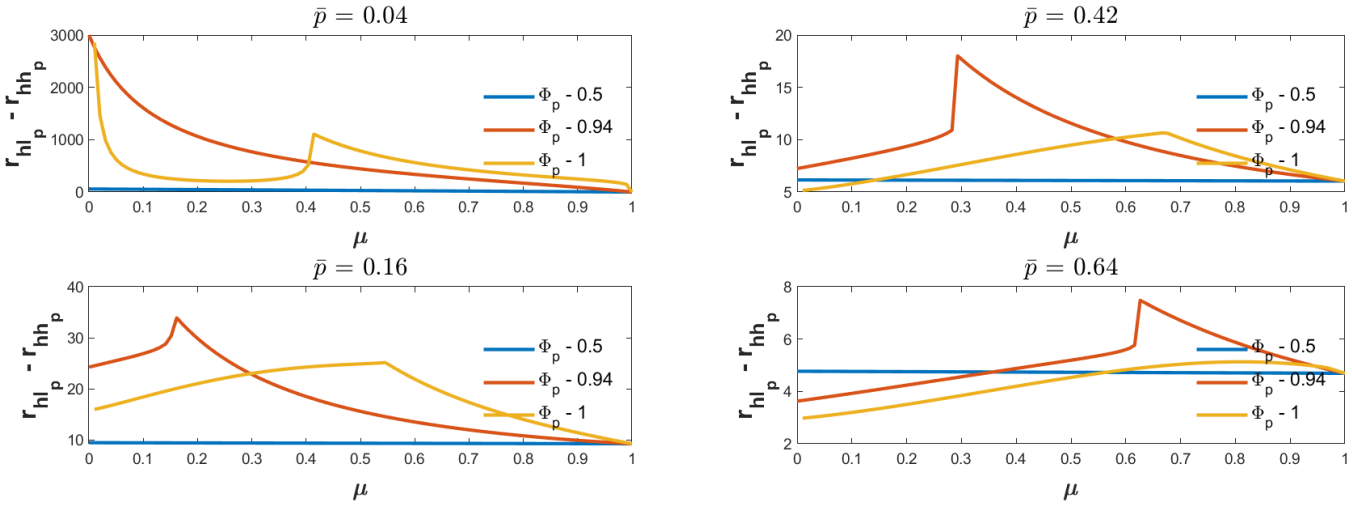

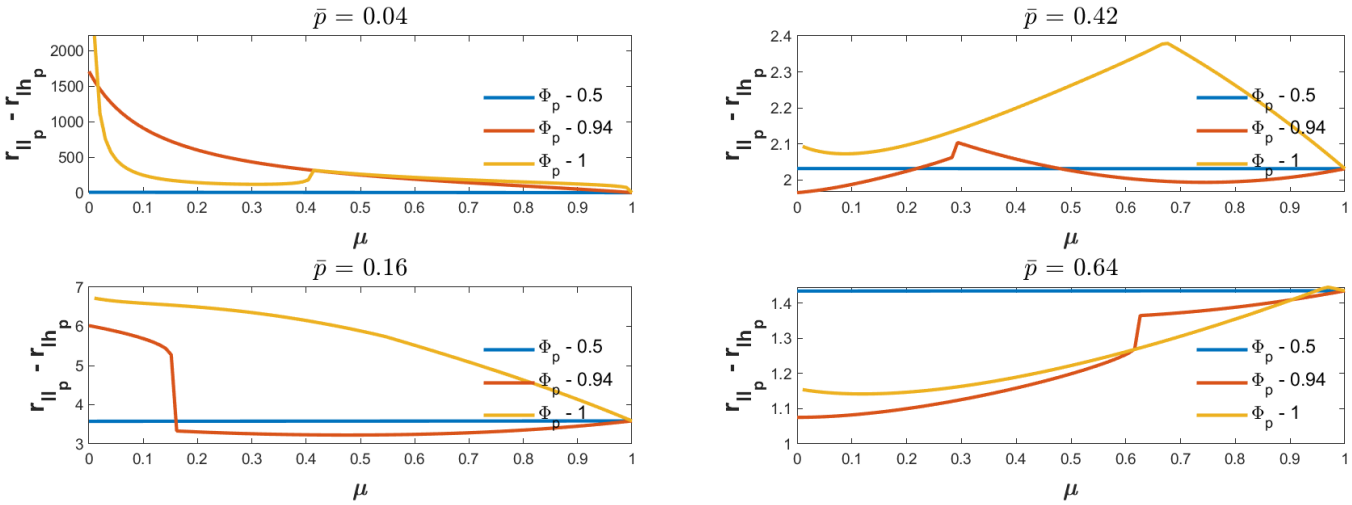

FIGURE 13. Interest rate differential and average borrower quality (for borrowers with $\eta = l$)

4. Conclusion

In this paper, I show the role industry-specific bank specialization plays in pricing transition risk. Specialized banks can better price regulatory components of climate transition risk for firms in the E.U., a region that has seen consistent activity on environmental regulations and climate disclosures over the past decade. I also show how specialized banks might not necessarily respond to an oil supply news shock, even though the shock is relevant for energy prices and, therefore, the returns of energy-intensive firms. I also show that this pattern is stronger after increased financial stress in the economy, implying that browner firms are more likely to receive favorable lending rates during times of aggregate financial stress.

I reconcile these empirical facts with a model of costly screening and underreaction to costless public information in a competitive bank lending framework. Through a higher capacity for information acquisition, specialized banks can better distinguish between the more and less exposed borrowers. However, banks' reaction to public information about transition risk can lead to interest rate differentials in favor of more exposed firms, conditional on the signal provided by the screening. I also discuss the effects of non-Bayesian updating on the specialized bank's optimal information acquisition. I show that during periods of poor average borrower quality, the specialized bank has a higher incentive to depend on private information, and the effect of underreaction on the decline in interest rate differential is even stronger.

This paper's empirical and theoretical results provide relevant insights into the mechanisms necessary to accelerate private financing of "green" projects. High-quality scientific and policy communication about climate change has still not been incorporated in lending decisions and may point towards inertia or underreaction by lenders in incorporating public signals about transition risks. Instead, policies that lower the costs of information acquisition by banks to understand the exposure of their borrowers to climate change will alleviate the information asymmetry across both specialized and non-specialized banks, resulting in more favorable financing terms for "green" or "carbon-neutral" firms. Policies in the form of comprehensive climate stress-testing frameworks or mandated disclosure of firms' emissions and carbon-risk exposure can provide significant insights for lenders to incorporate climate risks in their lending decisions.

Deal-Purpose F.E.	✓	✓	✓	✓

Note: This table reports estimates from the regression specification given in equation 1 estimated syndicated loan-level data for 2010-2022 for the entire sample. I estimate if firms with higher emission intensity face higher lending rates, whether banks specializing in the borrower's industry charge higher rates relative to non-specializing banks, and whether this effect is stronger 1 - 4 quarters after an oil supply news shock. The dependent variable is All-in-spread-drawn (bps). Borrower, Lender-Year, and SIC 2-digit industry-year fixed effects are included across all specifications. Firm-level controls include log of total assets of the borrower in US dollars, leverage ratio, ratio of capital expenditure to total assets, and the ratio of EBITDA to total assets. Loan-level controls include the maturity of the contract, whether the contract is secured, whether the contract has any covenants, and the log of the loan amount. Standard errors are clustered at the borrower level, and are reported in parentheses. The significance of coefficient estimates is indicated by *** for $p < 0.001$, ** for $p < 0.01$, * for $p < 0.05$.

Note: This table reports estimates from the regression specification given in equation 1 estimated syndicated loan-level data for 2010-2022 for firms headquartered in the U.S. I estimate if firms with higher emission intensity face higher lending rates, whether banks specializing in the borrower's industry charge higher rates relative to non-specializing banks, and whether this effect is stronger 1 - 4 quarters after an oil supply news shock. The dependent variable is All-in-spread-drawn (bps). Borrower, Lender-Year, SIC 2-digit industry-year, and Deal-Purpose fixed effects are included across all specifications. Firm-level controls include log of total assets of the borrower in US dollars, leverage ratio, ratio of capital expenditure to total assets, and the ratio of EBITDA to total assets. Loan-level controls include the maturity of the contract (logarithmic), number of lenders in the syndicate (logarithmic), whether the contract is secured, whether the contract has any covenants, and the loan amount (logarithmic). Standard errors are clustered at the borrower level, and are reported in parentheses. The significance of coefficient estimates is indicated by *** for $p < 0.001$, ** for $p < 0.01$, * for $p < 0.05$.

Note: This table reports estimates from the regression specification given in equation 1 estimated syndicated loan-level data for 2010-2020 for firms headquartered in the E.U. I estimate if firms with negative green technology-related exposure face higher lending rates, whether banks specializing in the borrower's industry charge higher rates relative to non-specializing banks, and whether this effect is stronger 1 - 4 quarters after a carbon price shock. The dependent variable is All-in-spread-drawn (bps). Borrower, Lender-Year, SIC 2-digit industry-year, and Deal-Purpose fixed effects are included across all specifications. Firm-level controls include log of total assets of the borrower in US dollars, leverage ratio, ratio of capital expenditure to total assets, and the ratio of EBITDA to total assets. Loan-level controls include the maturity of the contract (logarithmic), number of lenders in the syndicate (logarithmic), whether the contract is secured, whether the contract has any covenants, and the loan amount (logarithmic). Standard errors are clustered at the borrower level, and are reported in parentheses. The significance of coefficient estimates is indicated by *** for $p < 0.001$, ** for $p < 0.01$, * for $p < 0.05$.

Pricing Transition Risk after Financial Stress Post Oil Supply Shock

This section reports estimates from the regression specification given in equation 2 estimated syndicated loan-level data for 2010-2022 for firms headquartered in the E.U. and firms headquartered in the U.S. I estimate if firms with higher emission intensity, negative exposure to climate regulations, or negative exposure to green technologies face higher lending rates by banks specializing in the borrower's industry relative to non-specializing banks, and whether this effect changes 1 - 4 quarters after an oil supply news shock after a period of high financial stress. The dependent variable is All-in-spread-drawn (bps). Borrower, Lender-Year, SIC 2-digit industry-year, and Deal-Purpose fixed effects are included across all specifications. Firm-level controls include log of total assets of the borrower in US dollars, leverage ratio, ratio of capital expenditure to total assets, and the ratio of EBITDA to total assets. Loan-level controls include the maturity of the contract (logarithmic), number of lenders in the syndicate (logarithmic), whether the contract is secured, whether the contract has any covenants, and the loan amount (logarithmic). Standard errors are clustered at the borrower level, and are reported in parentheses. The significance of coefficient estimates is indicated by *** for $p < 0.001$, ** for $p < 0.01$, * for $p < 0.05$.

Appendix B. Proposition 2: Proof

For borrowers who received a low signal from private screening conducted by the S-bank in the first period:

$$F_{lh_p}(r) = 1 - \left[\frac{(p(hh_p)\bar{r}_{h_p} - 1)}{(p(hh_p)r - 1)}\right]$$

$$F_{ll_p}(r) = 1 - \left[\frac{(p(hl_p)\bar{r}_{l_p} - 1)}{(p(hl_p)r - 1)}\right]$$

$$\Rightarrow E\left[r_{ll_p}\right] - E\left[r_{lh_p}\right] = \int_{\bar{r}_{l_p}}^{R} r dF_{ll_p}(r) - \int_{\bar{r}_{h_p}}^{\bar{r}_{lh_p}} r dF_{lh_p}(r)$$

$$= \int_{\bar{r}_{l_p}}^{R} \frac{p(hl_p)\bar{r}_{l_p} - 1)p_{hl_p}}{(p(hl_p)r - 1)^2} r dr - \int_{\bar{r}_{h_p}}^{(\bar{r}_{lh_p}} \frac{(p(hh_p)\bar{r}_{h_p} - 1)p_{hh_p}}{(p(hh_p)r - 1)^2} r dr$$

$$= \frac{p(hl_p)\bar{r}_{l_p} - 1}{p(hl_p)}\left[ln\left(\frac{p(hl_p)R - 1}{p(hl_p)\bar{r}_{l_p} - 1}\right) - \left(\frac{1}{p(hl_p)R - 1} - \frac{1}{p(hl_p)\bar{r}_{l_p} - 1}\right)\right]$$

$$- \frac{p(hh_p)\bar{r}_{h_p} - 1}{p(hh_p)}\left[ln\left(\frac{p(hh_p)\bar{r}_{lh_p} - 1}{p(hh_p)\bar{r}_{h_p} - 1}\right) - \left(\frac{1}{p(hh_p)\bar{r}_{lh_p} - 1} - \frac{1}{p(hl_p)\bar{r}_{h_p} - 1}\right)\right]$$

which is $> 0 \quad \forall \quad \phi, \phi_p \geq \frac{1}{2} \quad$ and $\quad \mu \in [0,1]$

For borrowers who received a high signal from private screening conducted by the S-bank in the first period:

$$F_{hh_p}(r) = 1 - \left[\frac{(1 - p(lh_p)r)(p(hh_p)\bar{r}_{h_p} - 1)}{(p(hh_p)r - 1)^2}\right]\left[\frac{Pr(\eta = l|\eta_p = h_p)}{Pr(\eta = h|\eta_p = h_p)}\right]$$

$$F_{hl_p}(r) = 1 - \left[\frac{(1 - p(ll_p)r)(p(hl_p)\bar{r}_{l_p} - 1)}{(p(hl_p)r - 1)^2}\right]\left[\frac{Pr(\eta = l|\eta_p = l_p)}{Pr(\eta = h|\eta_p = l_p)}\right]$$

$$\Rightarrow E\left[r_{hl_p}\right] - E\left[r_{hh_p}\right] = \int_{\bar{r}_{l_p}}^{R} r dF_{hl_p}(r) - \int_{\bar{r}_{h_p}}^{\bar{r}_{lh_p}} r dF_{lh_p}(r)$$

$$= \int_{\bar{r}_{h_p}}^{\bar{r}_{lh_p}} r\left[\frac{(p(hh_p)\bar{r}_{h_p} - 1)}{(p(hh_p)r - 1)^2}\left((1 - 2\frac{Pr(\eta = l|\eta_p = h_p)}{Pr(\eta = h|\eta_p = h_p)})p(hh_p) + \frac{Pr(\eta = l|\eta_p = h_p)}{Pr(\eta = h|\eta_p = h_p)}p(lh_p)\,(p(hh_p)r + 1)\right)\right] dr$$

Substituting $Pr(\eta = l|\eta_p = h_p)$ and $Pr(\eta = h|\eta_p = h_p)$ as 'c' and 'd' respectively (for the compactness of expressions) and Substituting $Pr(\eta = l|\eta_p = l_p)$ and $Pr(\eta = h|\eta_p = l_p)$ as 'a' and 'b' respectively (for the compactness of expressions), we get

$$E\left[r_{hl_p}\right] - E\left[r_{hh_p}\right] = \left[\frac{\left(p(hl_p)\bar{r}_{l_p} - 1\right)\left(p(hl_p) + \frac{a}{b}p(ll_p)\right) + \frac{a}{b}\left(p(hl_p) - p(ll_p)\right)}{p(hl_p)^2}\right]ln\left(\frac{p(hl_p)R - 1}{p(hl_p)\bar{r}_{l_p} - 1}\right)$$

$$+ \left[\frac{\left(p(hl_p)\bar{r}_{l_p} - 1\right)\left(p(hl_p) + \frac{a}{b}\left(3p(ll_p) - 2p(hl_p)\right)\right) + \frac{a}{b}\left(p(hl_p) - p(ll_p)\right)}{p(hl_p)^2}\right]\left[\frac{1}{p(hl_p)\bar{r}_{l_p} - 1} - \frac{1}{p(hl_p)R - 1}\right]$$

$$+ \left[\frac{a}{b}\frac{\left(p(hl_p)\bar{r}_{l_p} - 1\right)\left(p(ll_p) - p(hl_p)\right)}{p(hl_p)^2}\right]\left[\frac{1}{\left(p(hl_p)\bar{r}_{l_p} - 1\right)^2} - \frac{1}{\left(p(hl_p)R - 1\right)^2}\right]$$

$$- \left[\frac{\left(p(hh_p)\bar{r}_{h_p} - 1\right)\left(p(hh_p) + \frac{c}{d}p(lh_p)\right) + \frac{c}{d}\left(p(hh_p) - p(lh_p)\right)}{p(hh_p)^2}\right]ln\left(\frac{p(hh_p)\bar{r}_{lh_p} - 1}{p(hh_p)\bar{r}_{h_p} - 1}\right)$$

$$- \left[\frac{\left(p(hh_p)\bar{r}_{h_p} - 1\right)\left(p(hh_p) + \frac{c}{d}\left(3p(lh_p) - 2p(hh_p)\right)\right) + \frac{c}{d}\left(p(hh_p) - p(lh_p)\right)}{p(hh_p)^2}\right]$$

$$\cdot\left[\frac{1}{p(hh_p)\bar{r}_{h_p} - 1} - \frac{1}{p(hh_p)\bar{r}_{lh_p} - 1}\right]$$

$$- \left[\frac{c}{d}\frac{\left(p(hh_p)\bar{r}_{h_p} - 1\right)\left(p(lh_p) - p(hh_p)\right)}{p(hh_p)^2}\right]\left[\frac{1}{\left(p(hh_p)\bar{r}_{h_p} - 1\right)^2} - \frac{1}{\left(p(hh_p)\bar{r}_{lh_p} - 1\right)^2}\right]$$

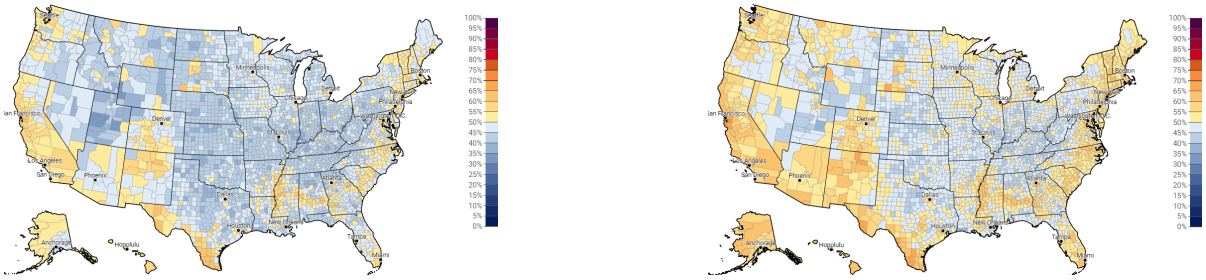

which is $> 0 \quad \forall \quad \phi, \phi_p \geq \frac{1}{2} \quad$ and $\quad \mu \in [0,1]$

Appendix C. Evidence of updates in beliefs about short-term and long-term risks from climate change

C.1. Data

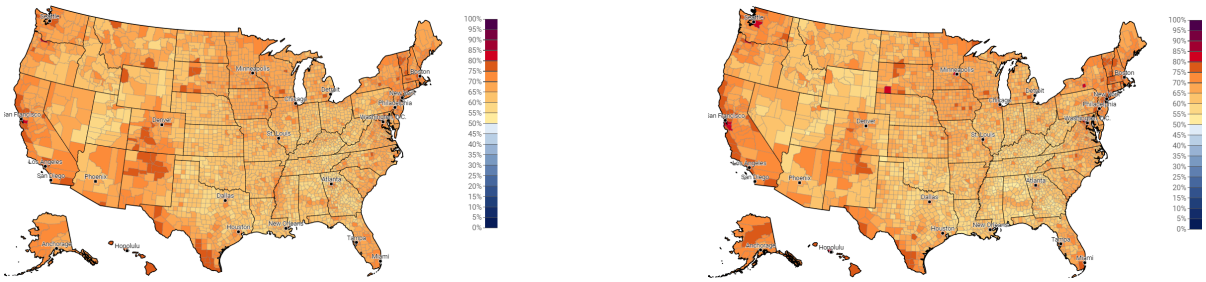

To understand if there is any under-reaction due to prior-conformity in the structure of belief updates in response to a climate event, I use county-level survey data on beliefs related to climate risk and potential damages from climate risk from **Yale Climate Beliefs** datasets (Howe et al. 2015). The estimates of county-level risk perceptions and opinions on policy are derived from a statistical model using multilevel regression with post-stratification on the national survey dataset, accounting for demographic and geographic population characteristics. I use data from the 2014 survey as an estimate of the prior beliefs. As an estimate for time-varying posterior beliefs, I use the data from the 2016, 2018, and 2020 surveys. Moreover, I also examine the changes in policy preferences to examine whether individual preferences update with major weather events, and whether the nature of this update is heterogenous across different climate policy instruments. I specifically focus on the following questions in the surveys:

a. Do you think that global warming is already harming people in the U.S. now or within ten years?
b. Do you think future generations are at risk of damage from climate change?
c. Do you support regulating CO_2 as a pollutant?
d. Do you support a policy requiring utilities to produce 20% electricity from renewable sources?

A. 2016 B. 2020

FIGURE A1. Short-term risk perceptions

A. 2016 B. 2020

FIGURE A2. Long-term risk perceptions

We can see from the maps above that the public opinion on these questions has evolved over the year, evidently in the direction of belief in climate change. For almost all of the questions on risk perception, the mean response grew between 2014 to 2020. The average percentage of people who think there are short-run risks from global warming increased from 39.67% in 2014 to 50.10% in 2020. The average percentage of people who believe there are long-run risks from global warming increased from 58.07% to 64.92%. (Table A2). Moreover, the average support for regulating CO_2 as a pollutant increased between 2014 and 2018 but declined in 2020 (Table A2).

I use the **Billion-Dollar Weather and Climate Disasters** report from NOAA[20]. The events covered in these reports account for greater than 80% of the damage that has been recorded from all U.S. weather and climate events.To examine the impact of Billion-Dollar weather events on beliefs/preferences in 2020, I used the total number of Billion Dollar events for the state to which the county belonged to for 2018 and 2019. I also control for the cumulative billion-dollar events between 2005 to 2017 to account for any long-term incorporation of information about climate change that may have resulted from more than a decade of large-scale weather-event-induced losses. From the descriptive statistics, we can see a noticeable variation in the number of these events across the states.

One of the significant caveats about using the YCM dataset is that despite the authors including census and election data into their model for accuracy, the estimated shifts in public opinion at the sub-national level between 2014 and 2020 may not only be due to opinion changes but also changes in demographics and weather anomalies that were relevant for modeling opinions about climate change.

I measure annual temperature and precipitation using the NCEI divisional data, containing quality controlled annual summaries of minimum and maximum temperature, and precipitation[21]. Annual averages are computed using equally weighted months. I calculate the difference of the maximum, minimum, and average temperature, and average precipitation from the 30 year average for the county to control for weather anomalies.

I measure demographic characteristics using the 5-year estimates from the 2019 American Community Survey 5-year estimates for county population, median household income, and percentage of people with more than 2 years of college education. For data on political affiliations, I use the MIT Election Data and Science Lab repository for official returns for the 2016 Presidential elections for all counties[22]. The dataset contains county-level vote shares for all candidates.

C.2. Methodology

I analyse the belief updating process in line with (Epstein et al. 2010) and (Cripps 2018), who present updated beliefs as a linear combination of the prior beliefs and the posterior beliefs.

$$\mu_t|x_t = (1-\lambda)\mu_0 + \lambda(\mu_t|x_t, x_{t-1}, x_{t-2}, ...)$$

where: μ_0 - prior belief ; $(\mu_t|x_t, x_{t-1}, x_{t-2}, ...)$ - Bayesian posterior on the basis of the information set available till time 't'. If there is no learning when subjected to new information, the individual's posterior beliefs are not significantly different from their prior beliefs ($\lambda = 0$). If the learning is Bayesian, then the posterior beliefs in the current period are the only determinants of the updated belief ($\lambda = 1$). In cases of non-Bayesian updating, $\lambda \in (0, 1)$.

This parameter could represent the confidence of the agent in the news, or the strength of the priors[23]. So, $\lambda < 1$ would imply that the agent is conservative in updating their beliefs when subjected to new information, whereas $\lambda > 1$ represents 'overconfidence' in the new information received. For the purpose of estimation, I assume that if the learning is perfectly Bayesian, the posterior beliefs in the current period are a combination of posterior beliefs in the previous period and new information being generated by the number of events occurring at the state-level. Taking into account all relevant controls, this would imply that the prior beliefs have no significant effect on the current beliefs.

Using the survey data, I examine the importance of the beliefs in the previous period ($PosteriorBelief_{t-1}$ where t = 2016 & 2018), the priors ($Belief_{2014}$), and the number of billion dollar events in the intermittent period between two survey waves, in determining the beliefs about the short-run and long-run risk perceptions across 3104 counties in the United States. The event count is a a proxy for a signal about climate risks - it is imperfectly informative about the risks. I control for local geographic conditions, population, educational attainment measures, and weather anomalies to account for possible non-linearities of effects of weather on risk perceptions. Since the waves measure the estimated percentage of people that say yes to the questions mentioned in the previous section, I look at the changes between the percentages recorded in waves after 2014 as posterior beliefs, and the percentage recorded in 2014 as the prior beliefs. If the posterior beliefs formed between 2016 and 2018 are strongly determinant of the beliefs iformed between 2018 and 2020, individuals have updated their risk perceptions.

[23]The updating could be iterated or 'one-shot'. For the purposes of this analysis, I am considering a one-shot Bayesian posterior

C.3. Results

C.3.1. Beliefs about Climate Risks

Table A4 presents the results from the regression of change in average short-run climate risk perceptions between 2018 and 2020 on the change in beliefs between 2018 and 2016, and the perceptions recorded in the first wave of the survey in 2014. The change in estimated percentage of people who believe that they are at risk from global warming between 2018 and 2016 is a proxy for the posterior beliefs in 't-1,' and the estimated percentage in 2014 is a proxy for the prior beliefs about short-run climate risk. In order to examine the effects of major climate-induced weather events on the update in beliefs, I check the impact of the frequency of billion-dollar weather events in 2018 and 2019, and the total number of events between 2005 and 2017, on the risk perceptions in 2020. Controlling only for state fixed effects (Specifications 1 and 2), I do not find a statistically significant effect of the recent events recorded in 2018 and 2018, or of the effect of the cumulative events recorded between 2005 and 2017 by themselves. However, these events have an interactive statistically significant positive effect for counties with higher posterior beliefs about short-run risk.

Across specifications 1 and 2, both the prior (2014 beliefs) and the previous period posterior (2018-2016 beliefs) play a statistically significant role in determining the update in beliefs between 2018 and 2020. The magnitude of the effect of the posterior beliefs is negative implying that the updated beliefs between 2020 and 2018 are growing at a slower pace, and the effect of the prior beliefs is positive. However, the effect of the posterior beliefs increases in the direction of higher short-term risk from climate change with large weather events in the recent past. This effect holds for the cumulative history of events between 2005 and 2017 as well, though the magnitude is smaller.

Controlling for the elevation, temperature, and precipitation anomalies for 2018 and 2019 (as compared to the 30-year county average), total population, educational attainment levels, and median household income, and the state fixed effects, does not lead to a change in the significance or the relative importance of the prior and posterior beliefs in the previous period in determining the update in beliefs between 2018 and 2019 (Specifications 3-6) [24].

However, the role of weather events become positive and statistically significant. The increase in the estimated percentage of adults between 2018 and 2020, who believe that the U.S. is at risk from climate change in the short-run, increases by 0.58-0.68 percentage points if the county belongs to a state that has experienced an additional event relative to other states in 2018 and 2019. Moreover, this effect is stronger by 0.015 percentage points in counties which have had a greater positive update about short-run risk perceptions betwene 2016 and 2018. The cumulative history of events between

[24] Note that these results hold when weather anomalies are accounted for in a quadratic form (Specifications 5 and 6), implying that controlling for possible nonlinear effects of weather anomalies does not reduce the belief-updating role of large-scale weather events and disasters.

2005 and 2017 has a positive, albeit smaller effect on the beliefs as well. However, as shown in specifications 4 and 6, the effect of the prior beliefs declines when the events between 2005 and 2017 are accounted for. This implies that not only do the weather events serve as a signal for individuals to update their beliefs in the direction of harm from climate change, but they also induce individuals to accord a higher weight to new information than their prior beliefs when thinking about short-term climate risk.

Examining the effect of the share of votes for the Republican party in the 2016 Presidential elections could provide evidence in favor of updating process being affected by the political beliefs of individuals in a county. However, I do not find any statistically significant effects of political beliefs on the change in short-term risk perceptions between 2018 and 2020. Table A3 presents the results from the regression of change in average long-run climate risk perceptions between 2018 and 2020 on the change in beliefs between 2018 and 2016, and the perceptions recorded in the first wave of the survey in 2014. The change in estimated percentage of people who believe that future generations are at risk from global warming between 2018 and 2016 is a proxy for the posterior beliefs in 't-1,' and the estimated percentage in 2014 is a proxy for the prior beliefs about long-run climate risk. Controlling only for state fixed effects (Specifications 1 and 2), I find a statistically significant positive effect of the recent events recorded in 2018 and 2019, and of the effect of the cumulative events recorded between 2005 and 2017 by themselves. Moreover, these events have an interactive statistically significant positive effect for counties with higher posterior beliefs about long-run risk.

Controlling for the elevation, temperature, and precipitation anomalies for 2018 and 2019 (as compared to the 30-year county average), total population, educational attainment levels, and median household income, and the state fixed effects, does not lead to a change in the significance or the relative importance of the prior and posterior beliefs in the previous period in determining the update in beliefs between 2018 and 2019 (Specifications 3-6) [25].

The increase in the estimated percentage of adults between 2018 and 2020, who believe that the U.S. is at risk from climate change in the short-run, increases by 0.56-1.08 percentage points if the county belongs to a state that has experienced an additional event relative to other states in 2018 and 2019. Moreover, this effect is stronger by 0.012 - 0.014 percentage points in counties which have had a greater positive update about short-run risk perceptions betwene 2016 and 2018. The cumulative history of events between 2005 and 2017 has a positive effect, and the magnitude of this effect is larger relative to that observed in table A4. The effect of the prior beliefs declines when the events in 2018 and 2019, as well as the events between 2005 and 2017 are accounted for. This again signals to beliefs about long-term risk being updated in presence of new information, but with the prior

[25]Note that these results hold when weather anomalies are accounted for in a quadratic form (Specifications 5 and 6), implying that controlling for possible nonlinear effects of weather anomalies does not reduce the belief-updating role of large-scale weather events and disasters.

beliefs and the beliefs in the previous period still playing an important role. In order to distinguish the news effects of these events from the monetary damages borne by individuals, I examine the possible effects of crop and property damages from weather-induced natural disasters across the United States between 2018 and 2019. The data on damages is acquired from the SHELDUS database, and includes per capita crop damages (in 2019 dollars) and per capital property damages (in 2019) dollars. I analyze quartile-wise impact of total crop and property damages in 2018 and 2019 on the updated beliefs between 2018 and 2020.

Controlling for the elevation, temperature, and precipitation anomalies for 2018 and 2019 (as compared to the 30-year county average), total population, educational attainment levels, and median household income, and the state fixed effects, I do not find any significant effects of the crop and property damages on the change in long-run perceptions about climate risks (Table A5). However, substantial property damages (or the fourth quartile of recorded property damages) have a positive significant effect when interacted with counties that had high posterior beliefs about short-term climate risks between 2016 and 2018 (Table A6). These results could provide some hints about the kind of information individuals pay attention to while forming their expectations about the long-run and short-run risks from climate change. While the occurrence of large weather events has a stronger impact on update in beliefs about long-run risks relative to the impact on short-run risks, monetary damages seem to only affect beliefs about short-run risks. Moreover, this impact is observable only for substantial property damages, in counties which already have a greater increase in posterior beliefs about short-run risks.

C.3.2. Policy Preferences

Tables A7 and A8 present the results of regression of policy preferences on the occurrence of the billion-dollar events. Controlling for all the county-level demographics, linear and quadratic weather anomalies, as well as state-level fixed effects, the results highlight that while the policy preference for CO_2 to be regulated as a pollutant is updating over time, with the posterior changes having a positive and significant effect, the weather events have no significant impact on these preferences. However, both the recent events and the cumulative event history between 2005 and 2017 have a positive and significant effect on the change in the percentage of people who support requiring utilities to produce 20% of electricity from renewable sources, with the magnitude of effect of recent events being larger. While I do not establish the link between beliefs and preferences, my analysis provides some preliminary evidence to think about the role weather events play in updating consumer preference for renewable energy, and hence accelerate the push for transition towards clean energy.

It is also interesting to notice, that while county-level poltiical beliefs did not have a significant role in expectation formation, they impact preferences for both CO_2 regulation and renewable-energy

based power sources. The impact of the share of republican votes in the 2016 general election is negative and statistically significant.

TABLE A2. Descriptive statistics
