The Private Capital Alpha

Gregory Brown* Andrei S. Gonçalves† Wendy Hu‡

This Version: July 2025§

Abstract

The alpha of an investment reflects its ability to improve the Sharpe ratio of a portfolio relative to a benchmark allocation. We argue that, in the context of private capital, the usual approach to estimate alpha is misleading because it ignores the economic realities of investing in private markets. We then combine a large sample of 5,028 U.S. buyout, venture capital, and real estate funds from 1987 to 2022 to estimate the alphas of private capital asset classes under realistic simulations that account for the illiquidity and underdiversification in private markets as well as the portfolio allocation of typical limited partners. We find that buyout as an asset class provided a significant annual alpha of 2.5% during our sample period. In contrast, over our sample period, the venture capital alpha was larger but statistically unreliable whereas the real estate alpha was smaller and also statistically insignificant.

§We are very grateful to MSCI and the Private Equity Research Consortium (PERC) for their support and access to the data used in this analysis. This paper benefited a lot from conversations with members of these institutions as well as from helpful comments from Isil Erel, Jun Chen, Mike Weisbach, Oleg Gredil, René Stulz, Spencer Couts, and seminar participants at the 2025 Midwest Finance Association (MFA) Meeting, 2025 IPC Current Issues in Alternatives Research Symposium, 2024 Inquire Europe, and 2023 IPC & PERC Private Equity Research Symposium.

Introduction

The allocation of institutional investors to private capital has drastically grown over the last decades. For instance, the aggregate target allocation of public pension funds to private capital has increased from around 8% in 2001 to around 22% in 2021 (Begenau, Liang, and Siriwardane (2023)). As such, measuring the risk-adjusted performance of private capital investments is extremely important. The usual approach in the literature is to estimate the Net Present Value (NPV) of private capital funds from the perspective of a Limited Partner (LP) who can freely allocate capital in public markets (see Kaplan and Schoar (2005) and Korteweg and Nagel (2016, 2024)). In contrast, we estimate the alpha of private capital asset classes from the perspective of a LP with realistic public market allocation. We also account for other economic realities of investing in private capital such as the effect of illiquidity and underdiversification on the allocation of LPs to private markets.

Our empirical analysis is based on the MSCI Private Capital (previously Burgiss) Universe dataset. We cover 5,028 U.S. Buyout (BO), Venture Capital (VC), and Real Estate (RE) private equity funds with vintage years from 1987 to 2022, representing $3.64 trillion in total fund commitments. We estimate the alpha of each of these private capital asset classes separately as well as the alpha of a value-weighted portfolio on these three asset classes combined (which we refer to as ALL).

Our main findings are as follows. First, the annualized alpha of BO over our sample period was positive (2.5%) and statistically significant (the 95% confidence interval covers from 0.1% to 4.5%). Second, while VC had a large annualized alpha over our sample (4.5%), the substantial uncertainty associated with VC investments makes this alpha statistically insignificant (the 95% confidence interval covers from -4.4% to 15.5%). And third, RE provided a smaller positive alpha (2.0%) that is also statistically insignificant (the RE confidence interval covers from -0.8% to 3.9%). With BO, VC, and RE combined, the ALL strategy delivered an annualized alpha of 2.9% that is close to statistically significant (the 95% confidence interval covers from -0.5% to 6.7%).

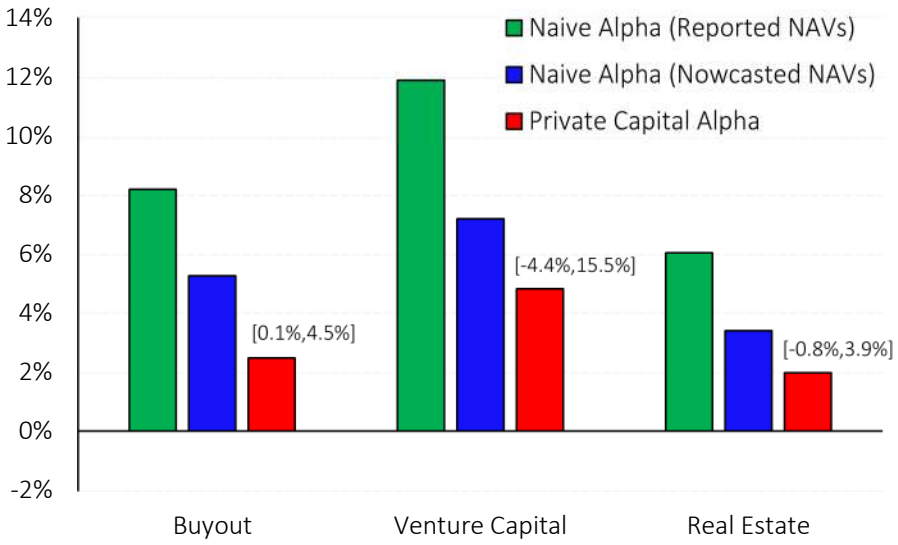

Figure 1
Main Result: The Private Capital Alpha

This figure provides the alphas of the private capital asset classes we study. The green and blue bars provide naive alphas based on regressions of private capital value-weighted indices onto equity and bond public market indices. The green bar computes private capital returns using reported NAVs whereas the blue bars use the nowcasted NAVs of Brown, Ghysels, and Gredil (2023) to correct for stale NAVs. The red bars provide alphas based on simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (with the median alpha used for the bars and the 95% confidence interval reported on the top of each bar). These alphas reflect the Sharpe ratio increase of a realistic portfolio that includes public and private investments relative to a baseline public market portfolio, normalized appropriately to be in alpha units.

A naive alpha estimation leads to very different results. To highlight this issue, we compute fund-level returns using reported cash flows and Net Asset Values (NAVs). We then aggregate fund-level returns into asset class returns as standard value-weighted indices. Finally, we estimate the alpha of each of these indices from the intercept of a regression of the respective index onto bond and equity public market indices. The results are provided in the green bars of Figure 1. The alphas are massive, with the lowest annualized alpha being a little higher than 6%. We refer to these values as "naive alphas" because they do not account for the economic realities of investing in private capital (detailed below).

One important economic reality of private capital investments is that reported NAVs are stale, which leads to understated risk and overstated risk-adjusted performance (see

Getmansky, Lo, and Makarov (2004) and Couts, Gonçalves, and Rossi (2024)). To address this issue, we consider an alternative naive alpha estimation that uses the nowcasted NAVs of Brown, Ghysels, and Gredil (2023) when computing fund-level returns, but is otherwise based on the same procedure described in the above paragraph. The results for this alternative naive alpha are provided in the blue bars of Figure 1. While alphas decrease after using nowcasted NAVs, the annualized alphas are still large, varying from 3.4% (for RE) to 7.2% (for VC). We argue that these are still "naive alphas" as they do not account for the economic realities of investing in private capital beyond NAV smoothing.

These naive alphas have two main limitations. First, the naive alphas are based on private capital indices that include all funds of each vintage year whereas evaluation and monitoring costs would limit the number of funds a realistic LP would invest in annually. That is, realistic private capital investments are underdiversified whereas the indices underlying naive alphas are well diversified. Second, the naive alphas implicitly reflect the Sharpe ratio increase in the maximum Sharpe ratio portfolio in public markets to the maximum Sharpe ratio portfolio that combines public and private market investments. A realistic LP would not hold the maximum Sharpe ratio portfolio of public market indices in the absence of private capital opportunities (due to mandates, constraints, and informational frictions). Moreover, a realistic LP controls the capital commitments to private capital, but not the actual weight allocated to private capital since capital calls and distributions are under the control of the General Partners (GPs). As such, a realistic LP can never reach a pre-specified and fixed allocation to private capital, let alone the maximum Sharpe ratio allocation that combines public and private market investments.

To address these limitations, our private capital alpha is based on simulations of realistic investments in private capital. Specifically, we simulate an LP that adds private capital investments to a pre-specified and realistic public market allocation that is not necessarily the maximum Sharpe ratio allocation (60% to equities and 40% to bonds in our baseline specification). The LP starts with 0% allocations to private capital in 1987 and commits capital to a small set of random private capital funds each vintage year (nine funds per year

in our baseline specification). The annual commitment is done as a fixed fraction of the LP's assets under management, with the LP holding the uncalled committed capital in a liquid asset (public equities in our baseline specification). The proportional annual commitment is calibrated so that the typical LP private capital allocation matches a pre-specified target private capital allocation in simulations (20% in our baseline specification). Nevertheless, the LP actual allocation to public and private markets in our simulations oscillates over time according to capital calls and distributions (which are the actual capital calls and distributions of the random set of funds the LP commits capital to over time). Given the time series of commitments within a simulation, we obtain the aggregate cash flows and NAVs of the LP each period and calculate the returns to the LP portfolio accordingly (with nowcasted NAVs used to compute private capital returns). Using these returns (after a ramp-up period of five years), we calculate the private capital alpha as the Sharpe ratio increase of the LP portfolio relative to the baseline public market portfolio, normalized appropriately to be in alpha units.

We perform the simulation in the prior paragraph 10,000 times, with the median alpha across simulations provided in the red bars of Figure 1. These numbers reflect the private capital alphas of the three asset classes under analysis. As it is clear from the figure, the private capital alphas are substantially lower than the naive alphas. We also add a bootstrap step to the simulations so that we can obtain confidence intervals that simultaneously account for the uncertainty associated with underdiversification and sampling variation. The 95% alpha confidence intervals are reported on the top of each red bar, with BO being the only asset class that provides a private capital alpha that is positive over the entire confidence interval. These results highlight the importance of accounting for the economic realities of private markets when estimating the alpha of private capital investments.

We also provide results under many alternative specifications, which change the method to deal with NAV staleness, the baseline public market portfolio, the target allocation to private capital, the number of funds the LP invests in each year, the ramp-up period considered, and the asset the LP uses for liquidity management. Overall, our message remains the same

throughout all specifications we consider: BO is the only private asset class we study that delivered a positive and statistically reliable alpha over our sample period.

Our main contribution is to provide a new method to evaluate the performance of private capital investments. In this regard, our innovation is threefold. First, instead of focusing on NPV measures such as the Public Market Equivalent (PME) of Kaplan and Schoar (2005), the Generalized PME (GPME) of Korteweg and Nagel (2016), or a GPME with better fund-level properties (Korteweg and Nagel (2024)), we estimate the alpha of private capital investments. This is important because capital allocation decisions require a comparison of risk-adjusted performance across asset classes. Alpha is the standard risk-adjusted performance metric for most asset classes. As such, having estimates for the alphas of private capital asset classes is essential to guide the allocation decisions of institutional investors.[1] Second, we focus on the risk-adjusted performance of private capital asset classes as opposed to fund-level risk-adjusted performance. While many investment decisions require fund-level risk-adjusted performance metrics, the decision of how much to allocate to private capital asset classes requires risk adjustment at the asset class level. It is not obvious how to translate the cross-fund distribution of NPV measures reported in the literature to the risk-adjusted performance of private capital asset classes. Third, our private capital alpha is based on an allocation to public and private markets that is realistic in the context of typical LPs of private capital funds. Moreover, it accounts for some of the economic realities of investing in private markets, such as underdiversification and the inability of LPs to control their effective allocation to private capital. These issues should translate into negative indirect cash flows (or extra discounting) when evaluating the NPV of a given private capital fund, but are generally not incorporated into NPV-type metrics in the prior literature.

We also contribute to the broader literature evaluating the performance of private capital

[1]Note that some papers introduce fund-level measures that they refer to as "alpha" (e.g., Korteweg, Panageas, and Systla (2022), Gredil, Griffiths, and Stucke (2023), and Korteweg and Nagel (2024)). However, these measures better reflect NPV or (components of) IRR than the Jensen's alpha concept generally used in the asset pricing literature. While there are important connections between NPV, IRR, and alpha (Korteweg, Panageas, and Systla (2022)), having a methodology to estimate the private capital alpha that is directly comparable to, say, the hedge fund alpha, is critical for portfolio allocation decisions.

investments (e.g., Kaplan and Schoar (2005), Pagliari Jr, Scherer, and Monopoli (2005), Harris, Jenkinson, and Kaplan (2014), Brown et al. (2015), Korteweg and Nagel (2016), Braun, Jenkinson, and Stoff (2017), Korteweg and Sorensen (2017), Brown and Kaplan (2019), Pagliari Jr (2020), Gupta and Nieuwerburgh (2021), Gredil (2022), Riddiough and Wiley (2022), Korteweg, Panageas, and Systla (2022), Brown, Ghysels, and Gredil (2023), Gredil, Griffiths, and Stucke (2023), Couts, Gonçalves, and Rossi (2024), Korteweg and Nagel (2024), and Couts and Gonçalves (2025)). Our main contribution to this literature is to provide the first evaluation of private capital as an asset class and from an alpha perspective while accounting for the illiquidity and underdiversification of private capital funds.

The rest of this paper is organized as follows. Section 1 discusses the economics of private capital investing and introduces our private capital alpha. Section 2 details the data and simulations we use to estimate the alphas of the different private capital asset classes. In turn, Section 3 presents our main empirical results and Section 4 explores alternative empirical specifications. Section 5 concludes. The Internet Appendix contains technical derivations and some details about our empirical analysis.

1 The Private Capital Alpha

In this section, we develop a framework to estimate the alpha of private capital investments. Subsection 1.1 highlights the major reasons why private capital investing is economically different from investing in public markets and Subsection 1.2 explains how we adjust the typical α estimation process to account for the economics of private capital investing.

1.1 The Economics of Private Capital Investing

Investment in private capital is largely done through private capital funds, which are investment vehicles structured as partnerships between the General Partner (GP) and the Limited Partners (LPs). In the typical structure, the investment decisions (such as sourcing, exe-

cuting, managing, and exiting investments) are delegated by the LPs to the GP. The LPs contractually commit to the private capital fund and can control the size and timing of the commitment. However, they do not control when the committed capital is called by the GP nor the fraction of the committed capital that is eventually called. Once called, the capital is deployed and locked up in the fund until distributed by the GP.

Given the above structure, there are (at least) three major characteristics of private capital investing that distinguish it from investing in public markets.

First, while it is relatively easy to invest in a well-diversified portfolio in public markets (e.g., through exchange traded funds), investing in private capital often results in underdiversification (see, e.g., Gredil, Liu, and Sensoy (2024)). Identifying and managing opportunities in private markets requires expertise and a substantial time commitment from the GP. As a consequence, each private capital fund tends to invest in relatively few assets. Moreover, diversifying across funds results in non-trivial monitoring costs for the LPs, which often come in the form of human capital investment. As a consequence, LPs tend to invest in relatively few funds, which themselves invest in relatively few assets, resulting in underdiversification.

Second, private capital investing is illiquid in nature. The contractual commitment between LPs and GP is long (typically in excess of 10 years), with LPs having no control over when capital is called and/or returned while having access to very limited secondary markets.[2] Consequently, allocations to private capital are subject to fluctuations that are partially out of the control of the LPs. For instance, suppose an LP commits 20% of its portfolio to a private capital fund. Until the capital is called, the LP's effective allocation to private capital is 0%. Then, let's say all the capital is called and in one year the private capital fund appreciates by 50% whereas the rest of the LP portfolio has a 0% total return. In this case, the LP's effective allocation to private capital becomes 30%. While this is an extreme example that ignores how diversification limits variability in the effective private

[2]Although the emergence of a secondary market for private capital funds has evolved steadily over the last 20 years, LPs facing liquidity needs who are forced to sell fund stakes during times of market dislocation can typically only do so at a significant discount to NAV and can face reputational penalties with GPs as well. For a detailed analysis of the secondary market for private equity, see Nadauld et al. (2019).

capital allocation of LPs, our empirical analysis shows that the portfolio allocation of LPs to private capital oscillates non-trivially around its target allocation even after accounting for realistic diversification.

Third, LPs face mandates and constraints when investing in private capital funds. For instance, investors cannot take short or levered positions in private capital funds as they can do in public markets (e.g., when investing in stocks). Moreover, while in principle the definition of accredited investors is broad enough to allow even (wealthy) retail investors to invest in private capital funds, in practice most private capital investment is done by institutional investors such as pension funds and endowment funds. These institutional investors face internal mandates and more strict constraints than the inability to take short or levered positions in private capital funds. As such, the overall weight that private capital can take in the typical LP portfolio faces restrictions that are not present for many investors when allocating capital to public markets.

1.2 The Private Capital Alpha: Definition and Computation

We now explain the typical α estimation process for liquid assets and how we adjust it to account for the economics of private capital investing described in the previous subsection.

Suppose an institutional investor (which we refer to as LP) has access to a public equity index and a public bond index, and is considering to also invest in private capital. To inform the decision process, the LP would like to understand the historical performance of the private capital market relative to these two public market indices (our approach can easily extended to LPs who have access to any number of public market indices).

Traditionally (i.e., if private assets were like public assets), the LP would approach this performance evaluation task by checking whether the intercept in a factor regression is zero. Specifically, letting r_t^* represent excess returns on a well-diversified private capital portfolio and $r_{p,t}^* = w_e^* \cdot r_{e,t} + (1 - w_e^*) \cdot r_{b,t}$ reflect excess returns on the ex-post maximum Sharpe ratio portfolio that can be formed with the public equity index (r_e) and the public bond index

(r_b), the LP can estimate the alpha intercept in the regression[3]

$$r_t^* \ = \alpha^* \ + \ \beta^* \cdot r_{p,t}^* \ + \ \epsilon_t^* \tag{1}$$

and check whether it is zero or not. If $\alpha^* > 0$ ($\alpha^* < 0$), then the historical performance suggests that the LP would have benefited from a positive (negative) allocation to private capital. In contrast, if $\alpha^* = 0$, then there was no benefit to private capital investing to the LP over the period of analysis.

While the alpha estimation framework above is widely applied in academia and in industry, we argue that it doe not properly account for the economics of private capital investing described in Subsection 1.1. To explain how we modify the alpha estimation process to deal with this issue, we start by noting that the α^* in Equation 1 can be alternatively written as

$$\alpha^* \ = sign[w^*] \cdot \sigma[\epsilon_t^*] \cdot \sqrt{\left|\mathbb{SR}[r_{pp,t}^*]^2 \ - \ \mathbb{SR}[r_{p,t}^*]^2\right|} \tag{2}$$

where $\mathbb{SR}[x_t] = \mathbb{E}[x_t]/\sigma[x_t]$ is the Sharpe ratio function and $r_{pp,t}^* = w^* \cdot r_t^* + (1 - w^*) \cdot r_{p,t}^*$ is the ex-post maximum Sharpe ratio portfolio that can be formed with r_t^* and $r_{p,t}^*$.[4]

Consequently, instead of estimating alpha from the factor regression in Equation 1, we rely on Equation 2 while adjusting it to deal with the underdiversification and illiquidity of private capital investments as well as the mandates and constraints faced by institutional investors. Specifically, we define the private capital alpha as

$$\alpha \ = sign[\Delta] \cdot \sigma[\epsilon_t] \cdot \sqrt{\left|\mathbb{SR}[r_{pp,t}]^2 \ - \ \mathbb{SR}[r_{p,t}]^2\right|} \tag{3}$$

where $\Delta = \mathbb{SR}[r_{pp,t}] - \mathbb{SR}[r_{p,t}]$,

$$r_{p,t} \ = w_e \cdot r_{e,t} + (1 - w_e) \cdot r_{b,t} \tag{4}$$

[3]If there are no arbitrage opportunities when trading on r_e and r_b, a Stochastic Discount Factor that perfectly prices these excess returns can be written as $M_t = a - b \cdot (\omega_e^* \cdot r_{e,t} + (1 - \omega_e^*) \cdot r_{b,t}) = a - b \cdot r_{p,t}^*$ (see Chapter 6 in Cochrane (2005)). As such, the intercept from a factor regression that includes r_e and r_b is equivalent to α^* in Equation 1, which uses only the maximum Sharpe ratio portfolio r_p^* as a factor. We rely on this result (which extends to any number of factor) as it simplifies our exposition.

[4]Equation 2, which we prove in Internet Appendix A (for a generic $r_{p,t}^*$), is a univariate version of the result in Gibbons, Ross, and Shanken (1989) linking pricing errors to mean-variance efficiency (see also the textbook treatment in Chapter 6.6 of Campbell, Lo, and MacKinlay (1997)). It is also used in Gonçalves, Loudis, and Ogden (2024) to study out-of-sample alphas of equity anomaly strategies.

and

$$r_{pp,t} \;= w_{t-1} \cdot r_t \;+\; (w - w_{t-1}) \cdot r_{liq,t} \;+\; (1 - w) \cdot r_{p,t} \tag{5}$$

Equation 3 contains three economic adjustments relative to Equation 2:[5]

1. It replaces the ex-post maximum Sharpe ratio public market portfolio (r_p^*) with an arbitrary public market portfolio (r_p).

2. It replaces the well-diversified private capital portfolio (r_t^*) with an underdiversified private capital portfolio (r_t).

3. It replaces the ex-post maximum Sharpe ratio private capital allocation (w^*) with an effective allocation of w_{t-1}, which targets a feasible allocation of w, but deviates from it given the LP's inability to trade on secondary markets or to control when capital is called or returned. The deviation from the target allocation ($w - w_{t-1}$) is invested in a liquid asset (r_{liq}) so that the LP can easily satisfy capital calls and allocate capital distributions that move it away from its target private capital allocation of w.

In a nutshell, Equation 2 measures the naive (i.e., factor regression) alpha from the Sharpe ratio increase obtained by moving from the maximum Sharpe ratio public market portfolio, $r_{p,t}^*$, to the maximum Sharpe ratio portfolio that also includes a well-diversified private capital portfolio, $r_{pp,t}^* = w^* \cdot r_t^* + (1 - w^*) \cdot r_{p,t}^*$. However, the inherent underdiversification and illiquidity of private capital markets as well as institutional investors' mandates and constraints likely make these two maximum Sharpe ratio allocations infeasible to many LPs. As such, Equation 3 instead measures the private capital alpha from the Sharpe ratio increase obtained by moving from a given (and feasible) public market portfolio, r_p, to another feasible portfolio, r_{pp}, but that also includes private capital. Importantly,

[5]Equation 3 also has two technical adjustment relative to Equation 2. First, it replaces $\sigma[\epsilon_t^*]$ with $\sigma[\epsilon_t]$, where $r_t = \delta + \beta \cdot r_{p,t} + \epsilon_t$. Second, it replaces $sign(w^*)$ with $sign(\Delta) = sign(\mathbb{SR}[r_{pp,t}] - \mathbb{SR}[r_{p,t}])$ to make the alpha signs in Equations 2 and 3 consistent. A negative w^* implies a negative α^* in Equation 2 and would also tend to lead to a negative α in Equation 3 through $sign(\Delta)$ because forcing a positive weight on r_t when w^* is negative is detrimental to the final portfolio's Sharpe ratio.

$r_{pp,t} = w_{t-1} \cdot r_t + (w - w_{t-1}) \cdot r_{liq,t} + (1 - w) \cdot r_{p,t}$ to account for the fact that the LP chooses the target allocation (w) through capital commitments but not the actual allocation each period (w_t), inducing a need for liquidity management.

[Figure 2 around here]

Figure 2 provides two diagrams summarizing the differences between the naive alpha and the private capital alpha discussed above (assuming positive alphas for simplicity). The most important observation of these diagrams is in Figure 2(b). The private capital target allocation (w) may be higher or lower than the ex-post optimal allocation (w^*) and both cases induce a decline in Sharpe ratio, and thus in alpha. Intuitively, w^* is the allocation that perfectly balances the expected return and diversification benefits and costs of private capital. So, deviating from it in either direction is costly. Interestingly, even if the LP has the ideal target allocation ($w = w^*$) there is still a decline in alpha because the actual allocation at each point in time (w_t), which the LP does not control, deviates from w^*, inducing an alpha loss.

[Figure 3 around here]

The two key parameters to estimate the private capital alpha are the public equity allocation within the public market portfolio (w_e) and the target allocation to private capital (w). We calibrate these parameters to $w_e = 0.60$ and $w = 0.20$. These values reasonably reflect what typical LPs have done historically (and thus must have been feasible given their institutional constraints). To demonstrate that, Figure 3 plots the aggregate allocation of US public pension funds from 2001 to 2022. The data come from the Center for Retirement Research at Boston College, with all measurement details provided in Internet Appendix B. Figure 3(a) starts by showing that public equities and fixed income together with the three private asset classes we study in this paper, buyout (BO), venture capital (VC) and real estate (RE), comprise most of the portfolio of US public pension funds. There is a slight decline over time on the total allocation to these asset classes, which is mainly explained by the increase in the allocation to other alternative asset classes that we abstract from in this

paper (hedge funds, commodities, private debt, and infrastructure). Still, the asset classes we consider always account for at least 90% of the total allocation of US public pension funds.[6] Figure 3(b) shows that the relative allocation to BO+VC+RE has increased over time, reaching a little above 20% in the latest years of our sample period. So, it is reasonable to assume a $w = 0.20$ target allocation to private capital (as the next section shows, in our simulations the LP starts with 0% and builds up towards the 20% target private capital allocation). Figure 3(b) also shows that the allocation to public equities (as a fraction of the allocation to public equities and fixed income) is only slightly above 60% (on average, 65.8%). So, the $w_e = 0.60$ calibration is also reasonable (and reflects the 60-40 public market split used as a benchmark in the industry). Subsections 4.2 and 4.3 provide results under different calibrations for the w_e and w parameters, respectively.

The next section details the data we use to measure r_b, r_e, and r_{liq}. It also explains the simulations we run (including the data used) to obtain w_t and r_t, which account for the underdiversification and illiquidity of private capital investments. Combined with the $w_e = 0.60$ and $w = 0.20$ calibration, each simulation leads to time-series for $r_{p,t}$ and $r_{pp,t}$, which allow us to calculate α from Equation 3 in each simulation. As such, our estimation approach leads to a distribution for the alphas that different LPs would have obtained historically due to the underdiversification embedded in r_t. We add sampling (i.e., statistical) variation on the top of this distribution through a bootstrap procedure to obtain alpha confidence intervals.

2 Data and Measurement for $r_{p,t}$ and $r_{pp,t}$

This section details the data and measurement approach we rely on to construct $r_{p,t}$ and $r_{pp,t}$. Subsection 2.1 explains how we construct our public market portfolio ($r_{p,t} = w_e \cdot r_{e,t} + (1 - w_e) \cdot r_{b,t}$), Subsection 2.2 details our dataset of private capital funds, and Subsection

[6] Note that public REITs are not included among the public asset classes we use to build r_p even though we also evaluate the alpha of private real estate. Figure 3(a) provides the reason. Specifically, the typical US public pension fund (and the typical institutional investor more broadly) holds a very small fraction of its portfolio in public REITs (which may be due to the relatively low weight of public REITs in the overall market portfolio). As such, public REITs are not essential in measuring the private capital alpha for the typical LP (albeit our framework can be easily extended to add public REITs to r_p).

2.3 elaborates on the simulations we use to construct the portfolio with allocation to both public and private markets, $r_{pp,t} = w_{t-1} \cdot r_t + (w - w_{t-1}) \cdot r_{liq,t} + (1 - w) \cdot r_{p,t}$.

2.1 The Public Market Portfolio: $r_{p,t}$

We construct $r_{p,t}$ from a portfolio that only invests in public equity and fixed-income funds since, as highlighted in Figure 3(a), these are the two major asset classes in public markets. Given our focus on U.S. private capital funds (see next subsection), our $r_{p,t}$ portfolio is based on the U.S. public markets, with allocations to two funds. For the public equity fund, we use the Vanguard Total Stock Market Index Fund (VTSMX) tracking the CRSP U.S. Total Market Index. For the fixed-income fund, we use the Vanguard Total Bond Market Index Fund (VBMFX) tracking the Bloomberg Barclays U.S. Aggregate Bond Index. Monthly return data for these two funds (net-of-fees) are obtained from the Center for Research in Security Prices (CRSP) mutual fund database and cumulated over each quarter to match the frequency of the private capital fund returns.[7]

To obtain excess returns on the equity and bond portfolios, which we label $r_{e,t}$ and $r_{b,t}$, we subtract from their respective net-of-fees returns the risk-free return over the same period. As a proxy for the risk-free return, R_f, we cumulate monthly returns on the 1-month Treasury bill each quarter, with monthly returns obtained from Kenneth French's data library.[8]

As discussed in Subsection 1.2, in our baseline analysis the public market portfolio has a 60-40 allocation to equities and bonds (i.e., $r_{p,t} = 0.6 \cdot r_{e,t} + 0.4 \cdot r_{b,t}$). To achieve this allocation, we assume that, at the end of each quarter, the institutional investor rebalances the portfolio to maintain a 60-40 public equity-bond allocation: if $r_{p,t}$ is over(under)allocated to the fixed-income fund, the institutional investor sells (buys) shares of the fixed-income fund and buys (sells) shares of the public equity fund. In Subsection 4.2, we explore alternative

[7] Since VTSMX was first offered to investors in April 1992 (after the beginning of our analysis), we extend it back to 1987 using returns on the CRSP value-weighted index minus a fixed management fee of 30 basis points annually. Although management fees for index mutual funds have declined significantly over the last decades, this level of fees is appropriate for this 1987 to 1992 period.

[8] See http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html.

public equity-bond allocations to understand how the private capital alpha varies across LPs that have different public market portfolios.

2.2 The Dataset of Private Capital Funds

Historically, one of the limiting factors on evaluating ex-post performance of private capital funds is the availability of high-quality data on private funds. In this paper, we obtain fund-level data from MSCI Private Capital (previously, Burgiss) Universe dataset, which covers a large sample of institutional-quality private funds. MSCI sources its data directly from institutional LPs, and its data has been used in recent studies of fund performance (e.g., Harris, Jenkinson, and Kaplan (2014) and Brown and Kaplan (2019)). For a detailed discussion of the advantages and potential biases of this database, see Brown et al. (2015).

We have access to the complete history of cash flows between LPs and each private capital fund, as well as fund quarterly reported valuations.[9] All data are net-of-fees and carried interest, and so represent the actual LP investment experience. We restrict the sample to U.S. funds classified as Buyout (BO), Venture Capital (VC), or Real Estate (RE). So, our final sample consists of 5,028 U.S. BO, VC, and RE private equity funds with vintage years from 1987 to 2022, representing $3.64 trillion in total fund commitments.[10]

[Table 1 around here]

[Figure 4 around here]

Table 1 provides an overview of our sample by vintage year and fund type. Our sample of 5,028 private capital funds is composed of 1,589 BO funds (with $2.23 trillion in committed capital), 2,403 VC funds (with $0.74 trillion in committed capital), and 1,036 RE funds

[9] As we discuss in Subsection 2.3.6, we also rely on quarterly nowcasted valuations from Brown, Ghysels, and Gredil (2023) to deal with the fact that reported valuations lead to smoothed returns, which in turn lead to understated risk and overstated risk-adjusted performance (see Getmansky, Lo, and Makarov (2004) and Couts, Gonçalves, and Rossi (2024)).

[10] We start in vintage year 1987 because this is the first vintage year with a sufficient number of private capital funds in the MSCI dataset.

(with $0.67 trillion in committed capital). There were relatively few funds available in the late 1980s and early 1990s, but investors could gain some within-vintage diversification by the later-half of the 1990s. Overall, private capital funds have experienced substantial growth since the 1980s. Figure 4 provides a quick visualization of this growth in private capital and also of the sample composition across the three fund types. The most important observation is that while most funds in our sample are VC funds, most capital in our sample is committed to BO funds.

2.3 The Public+Private Market Portfolio: $r_{pp,t}$

We consider four versions of $r_{pp,t}$ that vary based on the type of private capital funds the LP allocates capital to: (i) only BO funds, (ii) only VC funds, (iii) only RE funds, or (iv) all three types of funds jointly. For all four $r_{pp,t}$ versions, we assume that the LP has a target allocation of $w = 20\%$ to private capital in its portfolio as discussed in Subsection 1.2 (with Subsection 4.3 exploring alternative target private capital allocations). Moreover, we assume that capital commitment decisions are made annually even though we evaluate private capital investments based on quarterly returns.

As we discuss in Section 1, the necessary time commitment and monitoring costs involved in private capital investing tend to result in underdiversification. Moreover, the illiquidity of private capital funds makes it impractical to maintain a $w_t = 20\%$ allocation to private capital because of the uncertainty in future capital calls, distributions, and net asset values of the private capital funds. We accordingly design a strategy that allows for an effective private capital allocation (w_t) that targets $w = 20\%$ to an underdiversified portfolio (r_t), but that deviates from this $w = 20\%$ target allocation at every point in time, with the mismatched weight ($w - w_{t-1}$) allocated to a liquid asset ($r_{liq,t}$).

Specifically, we construct $r_{pp,t} = w_{t-1} \cdot r_t + (w - w_{t-1}) \cdot r_{liq,t} + (1 - w) \cdot r_{p,t}$, with the $r_{liq,t}$, w_t, and r_t components described in the subsections below. Our description focuses on the three versions of $r_{pp,t}$ with a single asset class each (i.e., BO, VC, or RE) and Subsection 2.3.5 explains how we adjust the measurement procedure when constructing the $r_{pp,t}$ version

that includes BO, VC, and RE jointly.

2.3.1 Measuring $r_{liq,t}$

When w_{t-1} deviates from $w = 20\%$, the LP needs to allocate a $w - w_{t-1}$ fraction of its total portfolio to a liquid asset to earn an excess return of $r_{liq,t}$ while having the flexibility to quickly move capital if needed. In our baseline analysis, we use $r_{liq,t} = r_{e,t}$ so that the LP relies on the public equity fund as its liquid asset. The key advantage of using $r_{liq,t} = r_{e,t}$ is that a negative $w - w_{t-1}$ requires no effective negative position on any asset since the large weight on $r_{e,t}$ in the public market portfolio, $r_{p,t}$, ensures that the $r_{pp,t}$ overall weight on $r_{e,t}$ is always positive in our simulations. As such, the LP effectively manages the private capital illiquidity challenge by adjusting the size of its long position on $r_{e,t}$ as needed without ever requiring a short position on any asset. Subsection 4.6 shows that the private capital alpha is very similar for LPs that instead use $r_{liq,t} = 0$ (i.e., LPs that rely on the risk-free asset for liquidity), but in practice cash represents only a small fraction of the allocation of US public pension funds (one average, 1.9%).

2.3.2 Measuring w_t, r_t, and $r_{pp,t}$

The LP targets an allocation in which 20% of the total portfolio is invested in private capital funds (with the public portion of the portfolio having the same 60-40 split as r_p). To achieve this target $w = 0.20$ allocation, we assume that the LP follows the simple strategy of committing a fixed fraction of its Assets Under Management (AUM), c, each year to private capital funds with inception in that year. For now, we take c as given and explain in Subsection 2.3.4 how we calibrate it.

Given an annual commitment rate of c, we need to define which funds the LP commits capital to and how much is committed to each fund. We assume that the LP is somewhat (but not completely) diversified in that it allocates capital to 9 funds each year and holds its stakes during the entire lives of the funds, which leads to a typical private capital portfolio with more than 100 funds (e.g., if all funds had the median life of 16 years from Table

1, the private capital portfolio would have 144 funds in steady state).[11] The 9 funds are selected randomly from the pool of funds with inception in the respective year (in BO, VC, or RE depending on the $r_{pp,t}$ version).[12] We further assume that the commitment decision for vintage year v is made at the end of the last quarter of calendar year $v-1$ so that the relevant committed capital is set aside (i.e., invested in $r_{liq,t}$) right before year v.[13] Moreover, we assume that the LP value-weights the commitments across funds.[14]

The above paragraph describes the selection of funds and how capital is distributed across funds. These decisions then allow us to calculate the fraction of each fund owned by the LP. Specifically, letting I_v define the set of funds with vintage year v selected by the LP, we have

$$\pi_i^{(v)} = \begin{cases} 0 & if\ i \notin \mathrm{I}_v \\ \pi^{(v)} & if\ i \in \mathrm{I}_v \end{cases} \tag{6}$$

with

$$\pi^{(v)} = \frac{c \cdot \mathrm{AUM}^{(v-1)}}{\mathrm{Size}^{(v)}} \tag{7}$$

where $\pi_i^{(v)}$ is the fraction of fund i owned by the LP (which is the same for all funds in I_v), $\mathrm{Size}^{(v)} = \sum_{j \in \mathrm{I}_v} \mathrm{Size}_j$ reflects the total capital commitment of the funds with vintage year v selected by the LP, and $\mathrm{AUM}^{(v)}$ reflects the LP's AUM at the last quarter of calendar year v (so that the commitment decision associated with vintage year v is made at the end of calendar year $v-1$).

Then, assuming all private capital funds are liquidated no later than 20 years after in-

[11] For vintage years with less than 9 funds, we assume that the LP commits capital to all funds available. While the focus on 9 funds per vintage year is somewhat arbitrary, Subsection 4.4 provides a comparative statics exercise that varies the number of funds the LP commits capital to annually, which helps us understand how the private capital alpha varies with the level of diversification in the private capital portfolio.

[12] Since our objective is to estimate the overall alpha of private capital investments, we implicitly assume that the LP has access to all available funds but no skill in selecting funds (which justifies the random selection of funds).

[13] Given the typical fundraising timeline for private funds, it is realistic to assume that investors often know which GPs will be raising new funds in the coming year.

[14] Given the large within-vintage heterogeneity in private fund sizes, it is unlikely that an LP can follow an equal-weighted commitment strategy (i.e., commit the same amount to each fund).

ception (which is consistent with our data), we calculate w_t and the private capital portfolio quarter t return based on

$$w_t = \frac{\sum_{v=y_t-20}^{v=y_t} \pi^{(v)} \cdot \text{NAV}_t^{(v)}}{\text{AUM}_t} \tag{8}$$

and

$$R_t = \frac{\sum_{v=y_t-20}^{v=y_t} \pi^{(v)} \cdot \left(\text{NAV}_t^{(v)} + \text{CF}_t^{(v)}\right)}{\sum_{v=y_t-20}^{v=y_t} \pi^{(v)} \cdot \text{NAV}_{t-1}^{(v)}} \tag{9}$$

where $\text{NAV}_t^{(v)} = \sum_{i \in \text{I}_v} \text{NAV}_{i,t}$, and $\text{CF}_t^{(v)} = \sum_{i \in \text{I}_v} \text{CF}_{i,t}$ reflect the Net Asset Value (NAV) at the end of quarter t and the net cash flow (CF) over quarter t for all funds with vintage year v selected by the LP. Moreover, y_t is the year associated with quarter t.

Finally, we measure excess returns on the LP's private capital portfolio by $r_t = R_t - R_{f,t}$ and $r_{pp,t}$ from Equation 5.

2.3.3 Diversification and Sampling Simulations

Since the choice of the 9 funds that the LP commits capital to each year (i.e., the set I_v) is random, we obtain w_t and r_t (and consequently $r_{pp,t}$) through simulations. Consider the simulation starting at the end of quarter $t-1$, which is the last quarter of year y_{t-1}. We know AUM_{t-1} and w_{t-1} (as well as the history of $\pi^{(v)}$ values for all $v \leq y_{t-1}$). We start by selecting 9 funds of the given category (BO, VC, or RE) randomly to enter $\text{I}_{v=y_t}$ among all funds of the given category with vintage year $v = y_t$ (with equal probability and no replacement) and calculate $\pi^{(v=y_t)}$ based on Equation 7. We then calculate the return on the private capital portfolio based on Equation 9, which allows us to obtain $\text{AUM}_t = (R_{f,t} + r_{pp,t}) \cdot \text{AUM}_{t-1}$ with $r_{pp,t}$ measured from Equation 5. We then have AUM_t, $\text{I}_{v=y_t}$, and $\pi^{(v=y_t)}$, and we calculate w_t based on Equation 8. At this point of the simulation, we know AUM_t and w_t (as well as the history of $\pi^{(v)}$ values for all $v \leq y_t$) and repeat the process above until we reach the last year in the simulation. Importantly, while weights and returns are updated every quarter, we only update $\text{I}_{v=y_t}$, and $\pi^{(v=y_t)}$ at the end of the fourth quarter of each year of the simulation.

We initiate our simulation in t = 1987Q1 with the assumption that $\text{AUM}_{1986\text{Q4}}$ = \$1

and $w_{1986Q4} = 0$. The assumption that $\text{AUM}_{1986Q4} = \$1$ reflects a normalization while the assumption that $w_{1986Q4} = 0$ captures the realistic idea that most LPs had little to no private capital allocation in their portfolios in the early 1980s. Finally, our α measurement starts after a "ramp-up" phase of five years (i.e., in 1992Q1) to allow w_t to be non-negligible since $\alpha = 0\%$ would hold by construction if we had $w_t = 0$.[15]

The simulations described above deal with underdiversification. That is, they allow us to study the variability associated purely with the fact that the LP commits capital to a subset of the available funds each year. However, these simulations do not deal with the (more standard) sampling variability linked to the fact that the data we actually observe is a sample of the data that we could have observed. For instance, if the lowest annualized α across the simulations in the prior paragraph is 1% and our sample is from 1987 to 2022, this result implies that an LP that followed the strategy we outline to construct $r_{pp,t}$ over the period from 1987 to 2022 would get an annualized α of at least 1%. However, such a result does not tell us much about the distribution of potential αs that the LP could have gotten if the data from 1987 to 2022 looked differently.

Consequently, we also perform a bootstrap simulation exercise to explore sampling variability. This bootstrap exercise compounds the variability due to underdiversification with the more general sampling variability described in the previous paragraph. Specifically, for each bootstrap simulation, we start by performing the diversification simulation to obtain the time-series for R_t and for

$$\text{NAVG}_t = \frac{\sum_{v=y_t-20}^{v=y_t} \pi^{(v)} \cdot \text{NAV}_t^{(v)}}{\sum_{v=y_t-20}^{v=y_t} \pi^{(v)} \cdot \text{NAV}_{t-1}^{(v)}}, \tag{10}$$

both of which are already random due to underdiversification. We then bootstrap with replacement the dataset composed of ($R_{f,t}$, $r_{liq,t}$, $r_{p,t}$, r_t, NAVG_t) holding fixed the first five years of the dataset (i.e., the ramp-up period).[16] Finally, given the first five years of w_t and

[15] The ramp-up of 5 years is a somewhat arbitrary measurement decision. However, Subsection 4.5 shows that the private capital alpha is similar for alternative reasonable ramp-up periods.

[16] We bootstrap in blocks of 4 quarters so that the sampling variability accounts for potential autocorrelation in returns (in untabulated results, we find that blocks of 12 quarters lead to similar findings).

the bootstrapped dataset of ($R_{f,t}$, $r_{liq,t}$, $r_{p,t}$, r_t, NAVG_t), we recursively construct

$$w_t = \frac{\sum_{v=y_t-20}^{v=y_t} \pi^{(v)} \cdot \text{NAV}_t^{(v)}}{\text{AUM}_t} = \frac{\text{NAVG}_t \cdot \sum_{v=y_t-20}^{v=y_t} \pi^{(v)} \cdot \text{NAV}_{t-1}^{(v)}}{(R_{f,t} + r_{pp,t}) \cdot \text{AUM}_{t-1}} = \frac{\text{NAVG}_t}{(R_{f,t} + r_{pp,t})} \cdot w_{t-1}$$

with $r_{pp,t}$ based on Equation 5.

We refer to the first type of simulations described in this subsection as our "diversification simulations" and the second type as our "sampling simulations". For both of them, we use 10,000 simulations. Consequently, for each statistic reported, we rely on the median value of the respective statistic across simulations. In some parts of our analyses, we also report 95% percentile Confidence Intervals (CIs), which are based on the simulation quantiles 2.5% and 97.5%.[17]

2.3.4 Determining c

We select the contribution rate, c, such that the median w_t matches the target $w = 0.20$ after the first ten years of simulation (because in the first years w_t is mechanically lower than w since $w_0 = 0$).[18] As such, c is not a free parameter, but rather a byproduct of the target weight parameter, w. Intuitively, the LP selects c in an attempt to match a desired target allocation to private capital. So, our simulations assume the LP is successful in terms of its median weight while allowing w_t to arbitrarily deviate from w over time as capital calls and distributions are out of the LP's control. In reality, LPs can design more sophisticated conditional contribution policies and determining the optimal contribution policy is an interesting area for future research.

[17] We adjust the bootstrap procedure to ensure that our diversification and sampling simulations have the same alpha estimate (i.e., median alpha). Specifically, letting α_d represent the alpha vector from the diversification simulations and α_b represent the alpha vector from the bootstrap simulations, all statistics reported for the bootstrap simulation rely on the distribution of $\alpha_b - median(\alpha_b) + median(\alpha_d)$, with an analogous adjustment for Sharpe ratios. We obtain similar confidence intervals for alpha using normal bootstrap confidence intervals, which are based on $CI(95\%) = [median(\alpha_d) \pm z_{0.975} \cdot \sigma(\alpha_b)]$, and thus require no bootstrap correction.

[18] The matching of the median w_t to w is done in an initial simulation without underdiversification (i.e., a simulation in which the LP invests in all funds of the given asset class raised in each vintage year). This approach ensures that the c value does not vary across the simulations. The details are provided in Internet Appendix C.

2.3.5 Adjustments for $r_{pp,t}$ version with BO, VC, and RE

For the $r_{pp,t}$ version in which r_t contains BO, VC, and RE jointly (which we refer to as ALL), we make some modifications in the capital commitment process. We assume that the LP still has a target weight of $w = 0.20$ for private capital but distributes its commitment each vintage year across asset classes in a value-weighted manner (i.e., based on the total capital being raised by each asset class in each vintage year). Specifically, the commitment (as a fraction of AUM) to asset class k associated with the vintage year v is $c_{k,v} = \phi_{k,v} \cdot \varphi_k \cdot c$, where c is the commitment parameter, the $\phi_{k,v} = \text{Size}_k^{(v)}/(\text{Size}_{\text{BO}}^{(v)} + \text{Size}_{\text{VC}}^{(v)} + \text{Size}_{\text{RE}}^{(v)})$ values are proportional to the capital being raised by each asset class, and the $\varphi_k = c_k^{ss}/(c_{\text{BO}}^{ss} + c_{\text{VC}}^{ss} + c_{\text{RE}}^{ss})$ values are proportional to the steady state commitment parameters (with details on how to obtain φ_k provided in Internet Appendix C). As before, c is chosen such that the median w_t matches the target $w = 0.20$ after the first ten years of simulation. Moreover, the LP continues to invest in 9 funds randomly, but requires 3 funds in each asset class, with commitments being value-weighted within each asset class.

2.3.6 Dealing with Stale NAVs

While the cash flows in our dataset properly reflect proceeds from and to LPs, the NAVs in our dataset (which are reported by the GPs) are only estimates of true NAVs. It is well known that illiquidity and incentive considerations can lead to stale NAVs, which in turn leads to understated risk and overstated risk-adjusted performance (see the discussions in Getmansky, Lo, and Makarov (2004) and Couts, Gonçalves, and Rossi (2024)). As such, when constructing the private capital returns in Equation 9 for performance evaluation, we use the nowcasted NAVs from Brown, Ghysels, and Gredil (2023).[19]

We use the reported NAVs for all other purposes (e.g., when constructing the weights in

[19]The only exception is that the $\sigma[\epsilon_t] = \sigma[r_t] \cdot \sqrt{1 - \mathbb{C}or[r_t, r_{p,t}]^2}$ term in Equation 3 is always obtained from private capital returns that use observed NAVs instead of nowcasted (or unsmoothed) NAVs. This approach ensures that NAV nowcasting (or unsmoothing) does not increase alphas through the idiosyncratic risk channel. However, we find similar (untabulated) alphas when using nowcasted NAVs in the $\sigma[\epsilon_t]$ calculation.

Equation 8, when updating AUM_t quarterly, and when calibrating c). The reason is that LPs make their allocation and liquidity decisions based on reported NAVs, not nowcasted NAVs. As such, when calculating the portfolios returns (r_{pp}) in Equation 5, our approach effectively assumes the LPs use weights (w_t) that are based on reported NAVs. Similarly, when computing $\text{AUM}_t = \text{AUM}_{t-1} \cdot (r_{pp,t} + R_{f,t})$, we assume the LP uses a $r_{pp,t}$ that is based on reported NAVs.

In many parts of our empirical analysis we also report results that rely entirely on reported NAVs. These results help us identify the effect of stale NAVs separately from the diversification, illiquidity, and LP constraint considerations we describe in Subsection 1.1.

Subsection 4.1 shows that our results are robust to dealing with stale NAVs using an adaptation of the 3-step unsmoothing method of Couts, Gonçalves, and Rossi (2024) to our setting. Further details about the nowcasted NAVs and 3-step unsmoothed NAVs we use are provided in Internet Appendix D, which also contains an analysis demonstrating that returns calculated using nowcasted or unsmoothed NAVs have much lower autocorrelation than the returns obtained using reported NAVs (note that strong return autocorrelation is a symptom of stale NAVs).

3 Main Empirical Results

This section details our main empirical results. Subsection 3.1 covers the distribution of private capital fund-level NPVs, Subsection 3.2 presents naive estimates of the alphas of private capital asset classes, and Subsection 3.3 provides our estimates of the alphas of private capital asset classes that account for the economic realities of investing in private capital.

3.1 The NPVs of Private Capital Funds

To start, we explore private capital performance at the fund-level to help us motivate the importance of estimating the private capital α, which focuses on the effect of adding private

capital (as an asset class) to the typical LP's portfolio.

The usual approach in the literature to measure the performance of a private capital fund is to estimate its Public Market Equivalent (PME) metric introduced in Kaplan and Schoar (2005). Korteweg and Nagel (2016) show that this PME metric can be seen as the Net Present Value (NPV) associated with the fund net cash flows using the Stochastic Discount Factor $\text{SDF}_t = exp(a - b \cdot log(R_{e,t}))$, where $R_{e,t}$ is the gross-return on an equity index and the parameters are restricted to $a = 0$ and $b = 1$.

[Table 2 around here]

Table 2 (Panel A) shows the distribution of these NPVs across our private capital funds in the BO, VC, and RE asset classes.[20] Each fund NPV is normalized by the present value of its negative cash flows (in absolute terms) so that the numbers can be interpreted as the NPVs relative to their respective investment sizes. On average, BO and VC produce positive NPVs (of 18% and 31% respectively) while RE produces a slightly negative NPV (of -6%). Since the performance distribution of private capital funds is very skewed, the median NPVs are perhaps more informative than the average NPVs. From the NPV quantiles, we have that the median NPVs are 13%, -16%, and -7% for BO, VC, and RE, respectively. The contrast between a positive average NPV and a negative median NPV for VC funds is due to the fact that VC performance is extremely skewed, with the 99% quantile of the distribution reflecting a NPV almost 900%.

While the NPVs in Panel A are informative, Korteweg and Nagel (2016) point out that restricting the SDF parameters to $a = 0$ and $b = 1$ can induce a non-trivial bias in the NPVs for funds with market betas that differ from one. They then propose a methodology to estimate a and b by requiring the SDF to perfectly price the equity and risk-free assets while accounting for the typical cash flow patterns in private capital funds. We estimate a and b separately for BO, VC, and RE funds following the methodology in Korteweg and

[20] For the NPV calculations, we use quarterly net cash flows and quarterly returns. Moreover, we rely only on funds with vintage year of 2012 or earlier so that we have at least ten years of cash flows by year 2022 (the end of our sample period). For funds with positive NAV at the end of 2022, we treat the final NAV as a terminal cash flow.

Nagel (2016) and report results in Table 2 (Panel B). The median fund performance in all three asset classes substantially deteriorates relative to Panel A, which suggests that the median fund in each of these asset classes has market beta above one (Korteweg and Nagel (2016) show that the approach in our Panel A overestimates fund NPV when the implicit fund market beta is above one). The average performance of RE funds improves, but this result is driven by the much longer right tail of the RE performance distribution in Panel B relative to Panel A.

Since our baseline alpha estimation relies on $r_{p,t} = 0.6 \cdot r_{e,t} + 0.4 \cdot r_{b,t}$ as the public market portfolio, we also estimate the fund-level NPVs using $\text{SDF}_t = exp(a - b \cdot log(R_{p,t}))$, with results reported in Table 2 (Panel C). The overall results suggest that the median performance further deteriorates for BO and VC and slightly improves for RE relative to Panel B. The average NPV of RE funds is 20%, but this result is driven by a further increase in the right tail of the RE performance distribution in Panel C relative to Panel B.[21]

Overall, Table 2 yields two clear results. First, most BO, VC, or RE funds provide negative NPV over our sample period once we properly control for public market risk (by estimating a and b instead of setting them to $a = 0$ and $b = 1$). Second, on average, BO and RE funds provide positive NPVs after controlling for public market risk. However, these average NPVs are largely driven by a relatively small fraction of funds with extremely good performance.

These findings provide very little guidance on whether adding private capital to an institutional investor's portfolio is beneficial. On one hand, most funds provide negative NPV. On the other hand, some funds provide very large positive NPVs that may justify investing in their entire asset class. Whether this is in fact the case is unclear, specially considering the underdiversification and illiquidity inherent in private capital investing, which creates non-trivial challenges in terms of achieving the performance that an optimal allocation could potentially deliver.

[21] Note that our bs associated with $log(R_e)$ (in Panel B) are quantitatively in line the bs reported in Korteweg and Nagel (2016, 2024). Our bs associated with $log(R_p)$ (in Panel B) are larger, but this is expected given the lower volatility of $log(R_p)$ relative to $log(R_e)$ as well as the fact that $log(R_p)$ is less correlated with private capital asset classes than $log(R_e)$ is.

Moreover, these NPV numbers are not directly comparable to the alpha estimates that LPs obtain for other asset classes. As such, it is hard for LPs to use these NPV numbers to guide decisions related to their target allocation to private equity. Consequently, we argue that providing a way for LPs to estimate the private capital alpha is essential for portfolio allocation decisions.

3.2 The Naive Private Capital Alpha

We now estimate the alpha of BO, VC, and RE markets while treating the underlying funds the same way researchers treat funds that invest in public markets (i.e., without taking into account the issues related to diversification, illiquidity, and LP constraints described in Subsection 1.1). We start by calculating fund returns and aggregating them to asset class returns (i.e., indices) to compute some basic return statistics.[22] We then regress the time series of returns of each asset class index onto public market factors and obtain the respective alpha from the intercept estimate of this regression. We call this factor regression alpha estimate the "naive alpha" as it reflects the alpha that is infeasible to most LPs (obtained from Equations 1 and 2).

[Table 3 around here]

Table 3 Panel A provides correlations between excess returns on each public market asset class (bonds and equities) and excess returns on each private market asset class (BO, VC, and RE), using both reported and nowcasted NAVs for private capital. The correlations between r_b and excess returns on private capital asset classes tend to be negative and

[22] Specifically, we build the quarter t return of each private capital asset class using

$$R_t = \frac{\sum_{v=y_t-20}^{v=y_t} \sum_{i=1}^{N_v} (\text{NAV}_{i,t} + \text{CF}_{i,t})}{\sum_{v=y_t-20}^{v=y_t} \sum_{i=1}^{N_v} \text{NAV}_{i,t-1}}$$

where N_v reflects the number of funds in the given asset class at vintage year v and y_t captures the year associated with quarter t. We obtain R_t from 1992 to 2022 so that the sample from this analysis is comparable to the sample over which the simulation statistics are calculated in the next subsection (which starts in 1992 due to the five year ramp-up period).

small, with the largest magnitude being from $\mathbb{C}or(r_b, r_{VC}) = -0.15$. In contrast, r_e has large correlations with private capital asset classes, with correlations of $\mathbb{C}or(r_e, r_{BO}) = 0.75$, $\mathbb{C}or(r_e, r_{VC}) = 0.47$, and $\mathbb{C}or(r_e, r_{RE}) = 0.26$ based on reported NAVs. The correlations with r_e significantly increase once we use nowcasted NAVs, becoming $\mathbb{C}or(r_e, r_{BO}) = 0.91$, $\mathbb{C}or(r_e, r_{VC}) = 0.70$, and $\mathbb{C}or(r_e, r_{RE}) = 0.67$, which indicates that the staleness of reported NAVs masks the public market risk present in private capital markets. Nevertheless, public markets and private markets are not perfectly correlated, which indicates that BO, VC, and RE can provide non-trivial diversification opportunities relative to public bonds and equities. Since diversification is an important component of the private capital alpha, this result suggests that private capital has the potential to provide a positive alpha.

Table 3 Panel B provides performance statistics for the different asset classes. Focusing on returns from reported NAVs, we see that the annualized Sharpe ratios of BO, VC, and RE are quite large (all substantially larger than the annualized Sharpe ratio of public equities). Similarly, all three private capital asset classes provide positive and large naive alphas relative to public markets whether we use $r_{e,t}$ or $r^*_{p,t} = w^*_e \cdot r_{e,t} + w^*_b \cdot r_{b,t}$ as the public market factor.[23] For instance, the annualized naive alphas relative to $r^*_{p,t}$ are $\alpha_{BO} = 8.2\%$, $\alpha_{VC} = 11.9\%$, and $\alpha_{RE} = 6.1\%$ (albeit the large VC alpha is statistically insignificant). These large alphas are partially due to the relatively small equity betas of the three private asset classes: $\beta^{(e)}_{BO} = 0.48$, $\beta^{(e)}_{VC} = 0.61$, and $\beta^{(e)}_{RE} = 0.13$.

Using nowcasted NAVs leads to higher estimated risk for private capital asset classes. For example, the annualized volatilities of BO, VC, and RE rise markedly following nowcasting (alongside stronger correlations with public markets, as previously noted). As such, the equity betas of these private asset classes increase significantly: $\beta^{(e)}_{BO} = 0.89$, $\beta^{(e)}_{VC} = 1.28$, and $\beta^{(e)}_{RE} = 0.41$.[24] Consequently, Sharpe ratios and naive alphas decline. Nevertheless, risk-adjusted performance is still quite positive. For instance, all three private capital asset classes

[23] Note that the alpha of private capital relative to $r^*_{p,t} = w^*_e \cdot r_{e,t} + w^*_b \cdot r_{b,t}$ is mathematically identical to the alpha of private capital relative to $r_{e,t}$ and $r_{b,t}$ in a multifactor model (see Footnote 3 for more details).

[24] Note that the equity betas for BO and VC that use nowcasted NAVs fall squarely within the range of values reported in the prior literature based on BO and VC funds (see Table 1 of Korteweg (2019)), which is not the case for the betas that use reported NAVs.

continue to have Sharpe ratios above the equity Sharpe ratio. Moreover, naive alphas are still large, with the annualized naive alphas relative to $r^*_{p,t}$ being $\alpha_{BO} = 5.3\%$, $\alpha_{VC} = 7.2\%$, and $\alpha_{RE} = 3.4\%$ (albeit, again, the large VC alpha is statistically insignificant).

3.3 The Private Capital Alpha

As we discussed in Section 1, estimating the alpha of private capital asset classes using factor regression alphas analysis (as we do in the prior subsection) does not account for important considerations related to diversification, illiquidity, and LP constraints. In this section, we provide results associated with the private capital alpha from simulations that account for these important considerations (as described in Section 2). As detailed in Subsection 2.3.3, we report median results across 10,000 simulation. Numbers in brackets reflect the 95% confidence interval for the given statistic based on the diversification simulation, which accounts for the uncertainty associated with the fact the LP commits capital to only 9 funds each vintage year (i.e., the LP is underdiversified). Numbers in parentheses provide the 95% confidence interval based on the bootstrap simulation that compounds the uncertainty associated with underdiversification and sampling.

[Table 4 around here]

Table 4 provides statistics on the performance of each asset class within simulations as well as on a value-weighted investment in all three private capital asset classes (under column "ALL"). The overall performance of private capital asset classes in these simulations is relatively similar to the performance of private capital indexes in Table 3. Nevertheless, the next to last row of each panel highlights the effect of underdiversification, which is not present in private capital indices. Underdiversification creates uncertainty even if we ignore sampling variability, with different hypothetical LPs having different performance simply due to the different funds they commit capital to each year (whereas with indices we implicitly consider an investment in all funds available each vintage year). For instance, while the typical LP obtains a Sharpe ratio of 0.78 over the sample period from its value-weighted private capital

investments, about 5% of the LPs experience Sharpe ratios below 0.57 or above 0.89 for the same strategy.

[Figure 5 around here]

Illiquidity affects the LPs ability to control their portfolio allocations to private capital (i.e., what weight of their portfolios is invested in private capital). Figure 5 shows the time-series of private capital weights (w_t) in the simulations. The black line provides the median w_t while the blue and red lines provide the w_t at quantiles 1% and 99% of the w_t distribution each period. In all cases, the contribution strategy targets a 20% allocation to private capital but the actual w_t oscillates over time. The first few years reflect the ramp-up period, with the private capital allocation starting at 0% and increasing towards 20%. Later periods have w_t closer to 20%, but also reflect large oscillations due to the inability of the LP to control GP's capital calls and distributions.

[Table 5 around here]

Table 5 Panel A shows the cross-simulation median for the average w_t after the ramp-up period of five years in each simulation. The average w_t is relatively close to the 20% target for all strategies: 18.3% for BO, 18.5% for VC, 19.9% for RE, and 17.7% for ALL. The averages tend to be slightly lower than 20% because LPs are not at steady state allocation after a ramp-up period of 5 years.

Table 5 Panels B and C provide the performance of each portfolio that combines public and private investments (r_{pp}), with the corresponding private capital alpha obtained from Equation 3 applied within each simulation. From Panel B, we have that all three private capital asset classes yield positive annualized alphas in most simulations if returns are obtained from reported NAVs. In particular, the 95% confidence intervals of all alphas in Panel B are composed almost entirely of positive numbers. In contrast, Panel C shows that, with returns based on nowcasted NAVs, only BO provides positive annual alphas in all simulations within the confidence interval (with the median alpha being 2.5% and the 95% confidence interval ranging from 0.1% to 4.5%). VC provides a large median annual alpha (of 4.8%), but the 95%

confidence interval goes from -4.4% to 15.5%, leading to no statistically reliable conclusion on the private capital alpha of VC over our sample period. Similarly, the median RE alpha is 2.0% but the 95% confidence interval goes from -0.8% to 3.9%. As a hybrid between the three asset classes, the value-weighted strategy that combines the three private capital asset classes provides a positive annual alpha in the vast majority of the simulations within the given confidence interval (the median alpha is 2.9% and the 95% confidence interval ranges from -0.5% to 6.7%).

[Figure 6 around here]

The alpha distributions across simulations can be visualized in Figure 6. As it is clear from Figure 6(b), which uses nowcasted NAVs, the BO and ALL alpha distributions mostly cover positive values. In contrast, the VC distribution covers a lot of negative values even though it is centered at a higher alpha than the BO distribution. Moreover, the RE distribution is centered at a lower alpha than the BO distribution and it also has more variability than BO, leading to a non-trivial fraction of negative alpha values.

Overall, the results suggest that the private capital alpha is substantially lower than the naive alpha analysis of the prior subsection indicates. In particular, over our sample period, only BO provided statistically reliable alpha (albeit much lower than the respective naive alpha).

4 Results based on Alternative Empirical Specifications

In this section, we report results on the private capital alpha of the three asset classes we study under alternative empirical specifications. These results serve as comparative statics analyses. In all cases, we report only private capital alphas from returns that correct for stale NAVs.

4.1 Alternative Methods to Deal with Stale NAVs

[Figure 7 around here]

Our baseline analysis uses the nowcasted NAVs of Brown, Ghysels, and Gredil (2023) to correct for stale NAVs. Figure 8 considers two alternative methods to deal with the same issue. They are both based on an adaptation of the 3-step unsmoothing method of Couts, Gonçalves, and Rossi (2024) to our setting (the details are provided in Internet Appendix D). The key difference between the two unsmoothing methods we consider is that the 3-step moving average (MA) unsmoothing method keeps the unsmoothing process as flexible as possible at the cost of a relatively large number of unsmoothing parameters (nesting the method in Getmansky, Lo, and Makarov (2004)) whereas the 3-step autoregressive (AR) unsmoothing method keeps the number of parameters small through a parametrization that is reasonable, but potentially mispecified (nesting the method in Geltner (1991, 1993)). Empirically, however, the two methods lead to very similar findings, as can be seen in Figure 8. Moreover, the results obtained using these unsmoothing methods are also similar to the ones obtained using nowcasting, with the exception that confidence intervals for VC (and, to a lesser extent, also for RE) tend to be wider under unsmoothing.

4.2 Alternative Public Market Portfolios

[Figure 8 around here]

Our baseline analysis relies on $r_{p,t} = w_e \cdot r_{e,t} + (1 - w_e) \cdot r_{b,t}$ with $w_e = 0.6$. Figure 8 provides the private capital alpha cross-simulation distribution under $w_e = 0.4$ and $w_e = 0.8$. The results under $w_e = 0.8$ are very similar to the baseline results. In contrast, the VC alpha displays a non-trivial decline when $w_e = 0.4$. However, the BO alpha increases slightly, keeping the ALL alpha quite stable across the different w_e values we explore.

4.3 Alternative Target Allocations to Private Capital

[Figure 9 around here]

Our baseline analysis relies on the private capital target weight of $w = 0.2$. Figure 9 provides the private capital alpha cross-simulation distribution under $w = 0.1$ and $w = 0.3$.

The results are very similar to our baseline results. In particular, in all calibrations, BO provided a statistically reliable positive alpha over the sample period, while VC and RE did not. Moreover, only a small fraction of simulations (but higher than 2.5%) led to a negative alpha for the value-weighted strategy that combines all three private capital asset classes.

4.4 Alternative Levels of Private Capital Diversification

[Figure 10 around here]

Our baseline analysis calibrates commitments based on LPs that commit capital to 9 funds each year. Figure 10 provides the private capital alpha cross-simulation distribution under alternative strategies in which the LP commits to either 3 funds each year or to all funds with vintage in that year. The main effect of the number of funds is that alpha uncertainty declines as the strategy becomes more diversified. Interestingly, even after considering a fully diversified strategy, VC and RE did not provide a statistically significant alpha over our sample period.

4.5 Alternative Ramp-up Periods

[Figure 11 around here]

Our baseline analysis estimates alphas after a ramp-up period of 5 years. Figure 11 provides the private capital alpha cross-simulation distribution under ramp-up periods of 1 year and 10 years. The alpha distributions tend to be similar regardless of the ramp-up period used, with two exceptions. First, longer ramp-up periods tend to induce more statistical uncertainty on the alpha estimates (because alphas are estimated over a shorter samples). Second, the BO alpha is higher under a 1 year ramp up period, which is a consequence of the relatively strong performance of BO in the first few years of our sample.

4.6 Alternative Liquid Asset

[Figure 12 around here]

Our baseline analysis estimates alphas using r_e as the liquid asset LPs invest their committed capital not yet called. Figure 11 provides the private capital alpha cross-simulation distribution under an alternative approach in which the LP invests in Treasury bills as their liquid asset. The results are relatively similar to our baseline results.

5 Conclusion

We combine a large sample of 5,028 U.S. buyout, venture capital, and real estate funds from 1987 to 2022 to estimate the alphas of private capital asset classes under realistic simulations that account for the illiquidity and underdiversification in private markets as well as for the portfolio allocation of typical limited partners. We find that buyout as an asset class has provided a positive and statistically significant alpha during our sample period. In contrast, over our sample period, the venture capital and real estate alphas were positive but statistically unreliable.

Our work provides a novel way to quantify the risk-adjusted performance of private capital investments. Our new method focuses on alphas (as opposed to NPV metrics), uncovers the benefit of private capital asset classes to typical limited partners, and accounts for the economic realities of investing in private markets. These three features make our private capital alpha an attractive risk-adjusted performance metric.

Moreover, our simulation method is flexible enough so that it can be easily adjusted to study questions outside the scope of this paper. For instance, our simulations can be adjusted to study the effect of liquidity shocks on the attractiveness of private capital investments. We hope this and other important questions can be addressed in future research building on our private capital alpha simulations.

Table 1

The MSCI Private Capital Funds used in our Analysis

This table provides the number of funds and total commitment to funds (in $ millions) by vintage year and private capital asset class. The table also provides the median life of funds in each vintage year. We use the MSCI data while keeping only funds with a US geographical focus. If there are less than five funds in a given asset class and vintage year, we do disclose the respective total commitment and median life of funds because of confidentiality restrictions with MSCI. Subsection 2.2 provides data details and a description of the results in this table.

Vintage	Buyout			Venture Capital			Real Estate			All		
Year	$	N	T	$	N	T	$	N	T	$	N	T

Table 2
NPVs of Private Capital Funds

This table shows the cross-fund distribution of Net Present Values (NPVs) using the Generalized Public Market Equivalent (GPME) metric of Korteweg and Nagel (2016), which is based on an SDF of the form $SDF_t = exp(a - b \cdot f_t)$, where f_t is the relevant risk factor. Panel A provides the PME metric of Kaplan and Schoar (2005) (in NPV terms), which is equivalent to the GPME with $a = 0$, $b = 1$, and $f_t = log(R_{e,t})$. Panel B provides the the GPME metric with a and b estimated separately for each asset class (without constraints), and $f_t = log(R_{e,t})$. Panel C provides the GPME metric with a and b estimated separately for each private asset class (without constraints), and $f_t = log(R_{p,t})$ with $R_{p,t} = 0.6 \cdot R_{e,t} + 0.4 \cdot R_{b,t}$. All NPV values are normalized by the present value of the fund negative cash flows (in absolute terms) so that the numbers can be interpreted as the NPVs relative to their respective investment sizes. Moreover, the table covers all three private capital asset classes we study: buyout (BO), venture capital (VC), real estate (RE). Subsection 2.2 provides data details and Subsection 3.1 provides a description of the results in this table.

PANEL A: $\mathbf{SDF_t = exp(0 - 1 \cdot log(R_{e,t}))}$

	a	b	N	Mean	Q1%	Q5%	Q10%	Q25%	Q50%	Q75%	Q90%	Q95%	Q99%

Table 3
Summary Statistics for Different Asset Classes: Correlations and Performance

This table provides basic risk and reward statistics for value-weighted public and private market indices from 1992 to 2022. The public market indices cover equities (e) and bonds (b). The private market indices cover buyout (BO), venture capital (VC), real estate (RE). The returns on the private market indices are obtained using reported NAVs (left side of the table) and nowcasted NAVs from Brown, Ghysels, and Gredil (2023) to adjust for stale NAVs (right side of the table). Panel A provides return correlations between the different asset classes. Panel B provides basic performance metrics. $\mathbb{E}[r]$ is the average excess return, $\sigma[r]$ is the excess return volatility, $\mathbb{SR} = \mathbb{E}[r]/\sigma[r]$ is the Sharpe ratio, $\beta^{(e)}$ and $\beta^{(b)}$ are the betas relative to r_e and r_b, $\alpha^{(e)}$ is the alpha relative to r_e, and $\alpha^{(e,b)}$ is the alpha relative to r_e and r_b (which is equivalent to the alpha relative to the maximum Sharpe ratio portfolio of r_e and r_b). We refer to the alphas in this table as "naive alphas" since they do not account for the economic realities of private capital investing (beyond stale NAVs). Subsection 2.2 provides data details and Subsection 3.2 provides a description of the results in this table.

Table 4
The Different Asset Classes in Simulations

This table provides basic risk and reward statistics for value-weighted public market indices as well as private capital investments that are realistic from the perspective of the typical Limited Partner (LP). The public market indices cover equities (e) and bonds (b). The private market investments cover buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The results are based on simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (see Section 2 for details on these simulations). For each statistic, we report median results across 10,000 simulation. Numbers in brackets reflect the 95% confidence interval for the given statistic based on the diversification simulation, which accounts for the uncertainty associated with the fact that the LP commits capital to only 9 funds each period. Numbers in parentheses provide the 95% confidence interval based on the bootstrap simulations that compound the uncertainty associated with underdiversification and sampling variation. $\mathbb{E}[r]$ is the average excess return, $\sigma[r]$ is the excess return volatility, and $\mathbb{SR} = \mathbb{E}[r]/\sigma[r]$ is the Sharpe ratio. Subsection 2.2 provides data details and Subsection 3.3 provides a description of the results in this table.

Table 5
The Total Portfolio (Public + Private) in Simulations

This table provides basic risk and reward statistics for a baseline public market portfolio and a portfolio that combines this public market portfolio with private capital investments. The public market portfolio is composed of 60% equities (e) and 40% bonds (b). The private market investments cover buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The results are based on simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (see Section 2 for details on these simulations). For each statistic, we report median results across 10,000 simulation. Numbers in brackets reflect the 95% confidence interval for the given statistic based on the diversification simulation, which accounts for the uncertainty associated with the fact that the LP commits capital to only 9 funds each period. Numbers in parentheses provide the 95% confidence interval based on the bootstrap simulations that compound the uncertainty associated with underdiversification and sampling variation. $\mathbb{E}[r]$ is the average excess return, $\sigma[r]$ is the excess return volatility, and $\mathbb{SR} = \mathbb{E}[r]/\sigma[r]$ is the Sharpe ratio. The private capital alpha is obtained from Equation 3 in each simulation. Subsection 2.2 provides data details and Subsection 3.3 provides a description of the results in this table.

(a) The Factor Regression Alpha

(b) The Private Capital Alpha

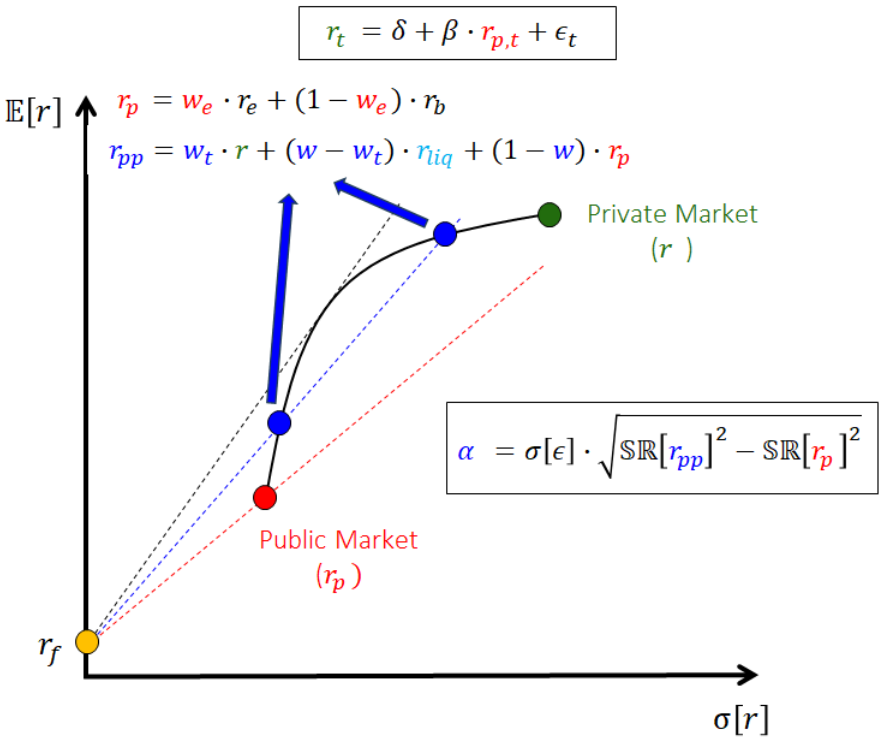

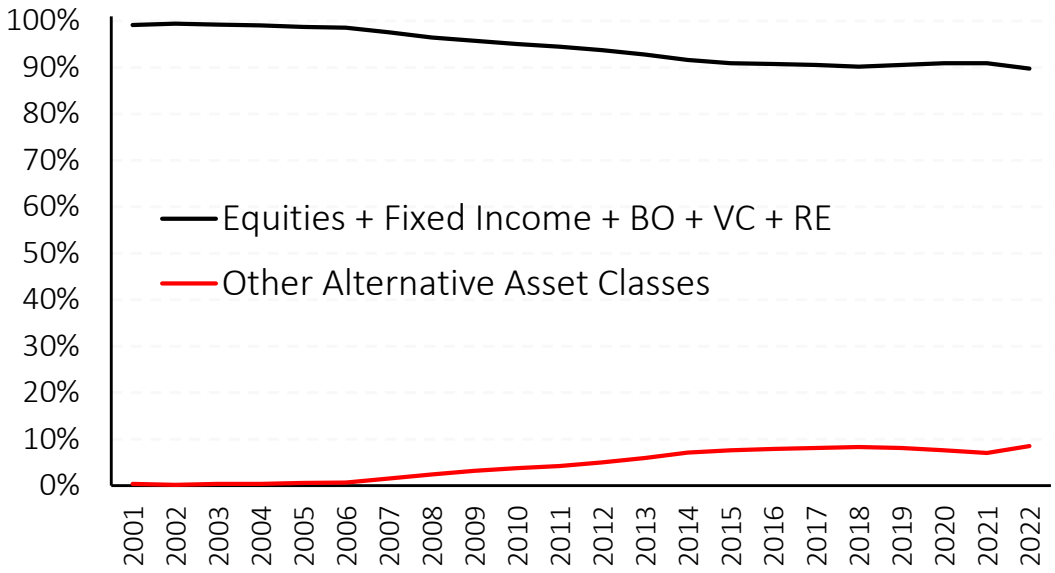

Figure 2
Differences Between the Factor Regression (or Naive) Alpha and the Private Capital Alpha

This figure provides two diagrams summarizing the differences between the factor regression alpha (which we refer to as naive alpha) and the private capital alpha proposed in this paper. The most important observation of these diagrams is that, when computing the private capital alpha, the private capital target allocation (w) may be higher or lower than the ex-post optimal allocation (w^*) and both cases induce a decline in Sharpe ratio (and thus in alpha) relative to what we obtain under the naive alpha. Subsection 1.2 provides the details underlying this figure.

(a) Portfolio Weight Relative to All Non-Missing Allocation

(b) Portfolio Weight Within the Asset Classes we Study

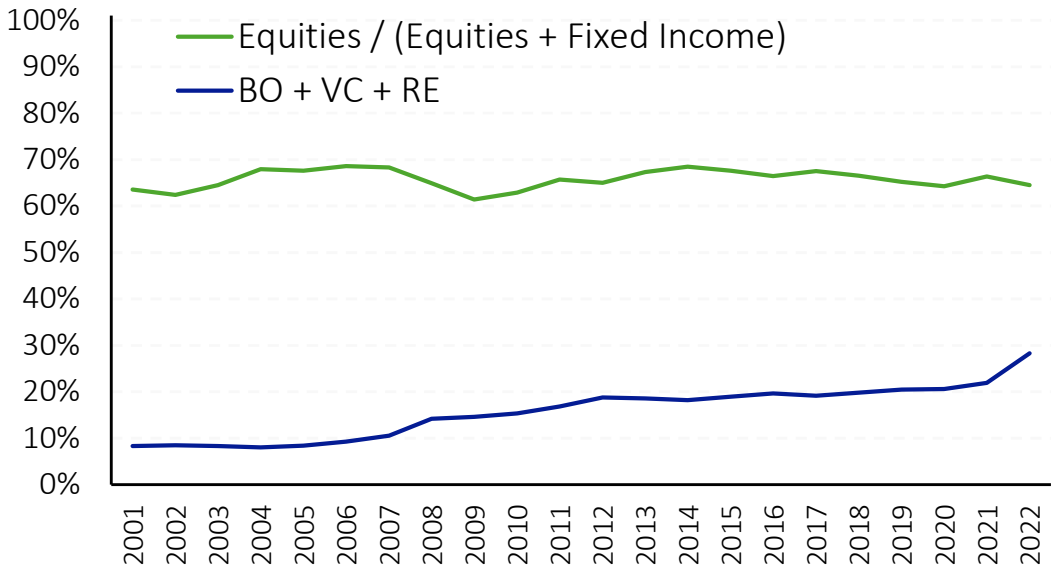

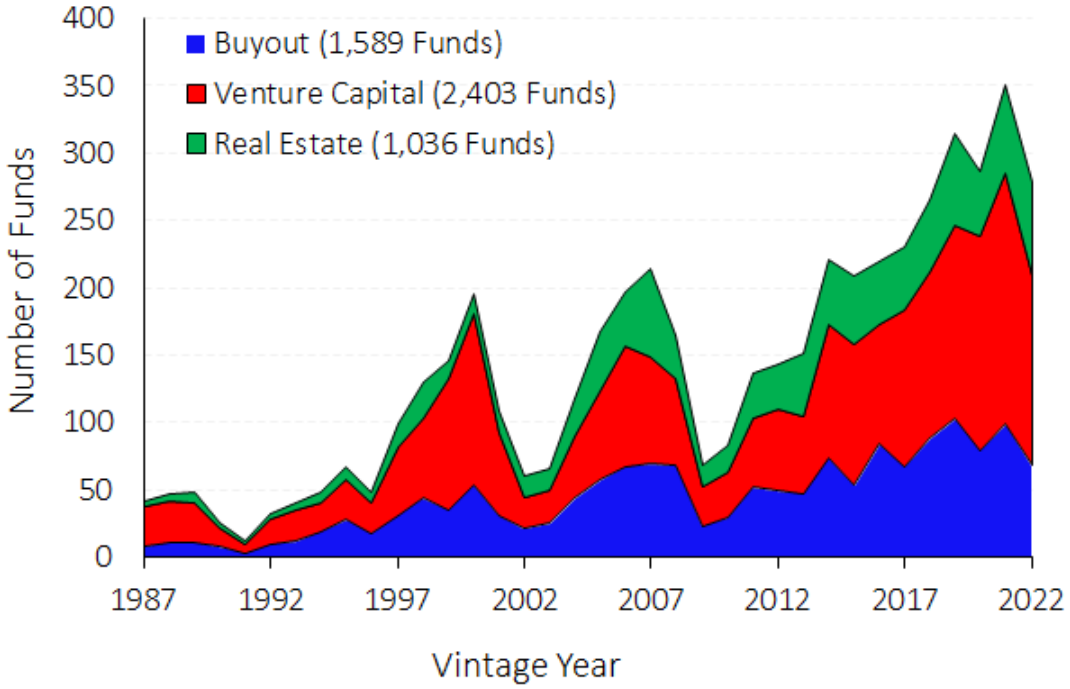

Figure 3
Allocation of US Public Pension Funds

This figure plots the aggregate allocation of US public pension funds from 2001 to 2022. The data come from the Center for Retirement Research at Boston College, with all measurement details provided in Internet Appendix B. Panel (a) provides (in the black line) the allocation of pension funds to public equities and fixed income together with the three private asset classes we study in this paper, buyout (BO), venture capital (VC) and real estate (RE) as well as (in the red line) the allocation of pension funds to other alternative asset classes we abstract from, which are hedge funds, commodities, private debt, and infrastructure. Panel (b) provides (in the blue line) the allocation of pension funds to BO+VC+RE as a fraction of the allocation to all five asset classes we study as well as (in the green line) the allocation of pension funds to public equities as a fraction of the allocation to public equities and fixed income. Subsection 1.2 provides a description of the results in this figure.

(a) Number of Funds by Fund Type

(b) Committed Capital by Fund Type

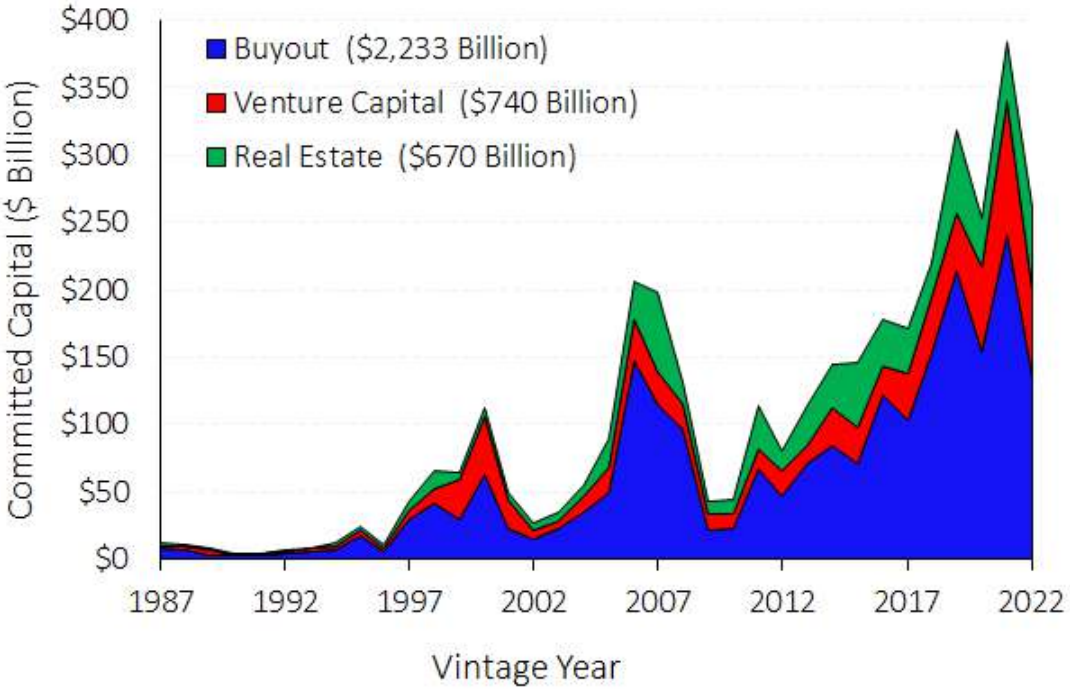

Figure 4
Number of Funds and Committed Capital by Fund Type

This figure plots the number of funds (Panel (a)) and the total commitment to funds in $ billions (Panel (b)) by vintage year and private capital asset class. We use the MSCI data while keeping only funds with a US geographical focus. Subsection 2.2 provides data details and a description of the results in this figure.

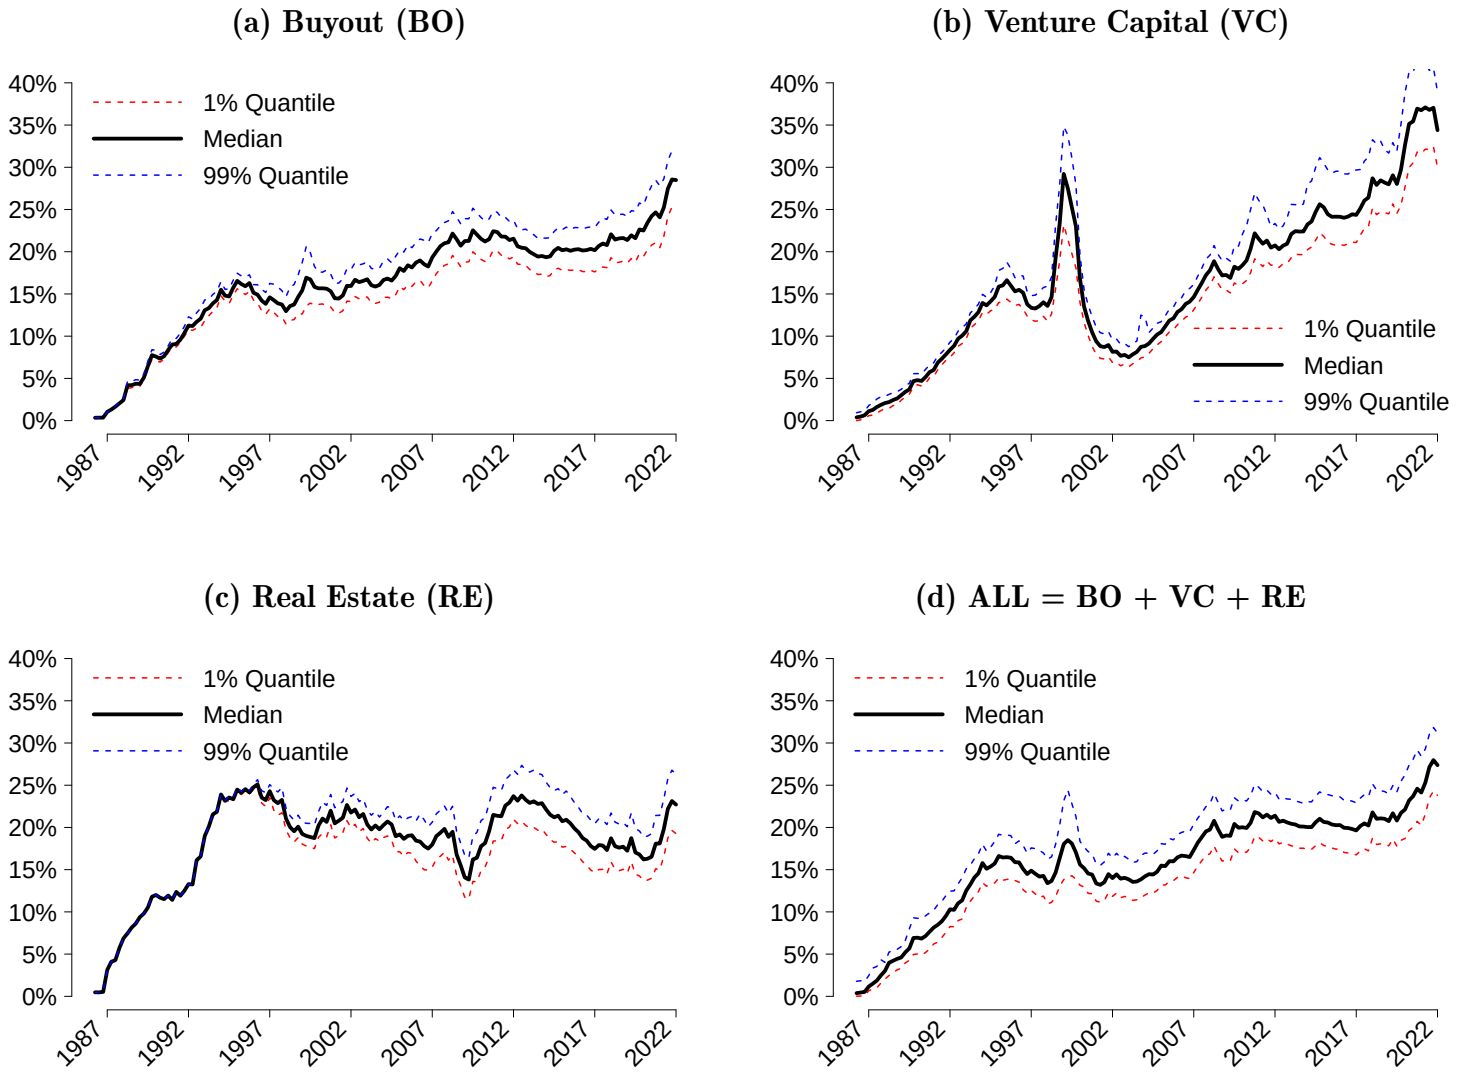

Figure 5
Private Capital Allocation Distribution

This figure plots the time-series of private capital weights (w_t) in the simulations for each private capital asset class: buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The black line provides the median w_t while the blue and red lines provide the w_t at quantiles 1% and 99% of the w_t distribution each period. In all cases, the contribution strategy targets a 20% private capital allocation but the actual w_t oscillates over time. The first few years reflect the ramp-up period, with the private capital allocation starting at 0% and increasing towards 20%. Later periods reflect large oscillations due to the inability of the LP to control GP's capital calls and distributions. Subsection 2.2 provides data details and Subsection 3.3 provides a description of the results in this figure.

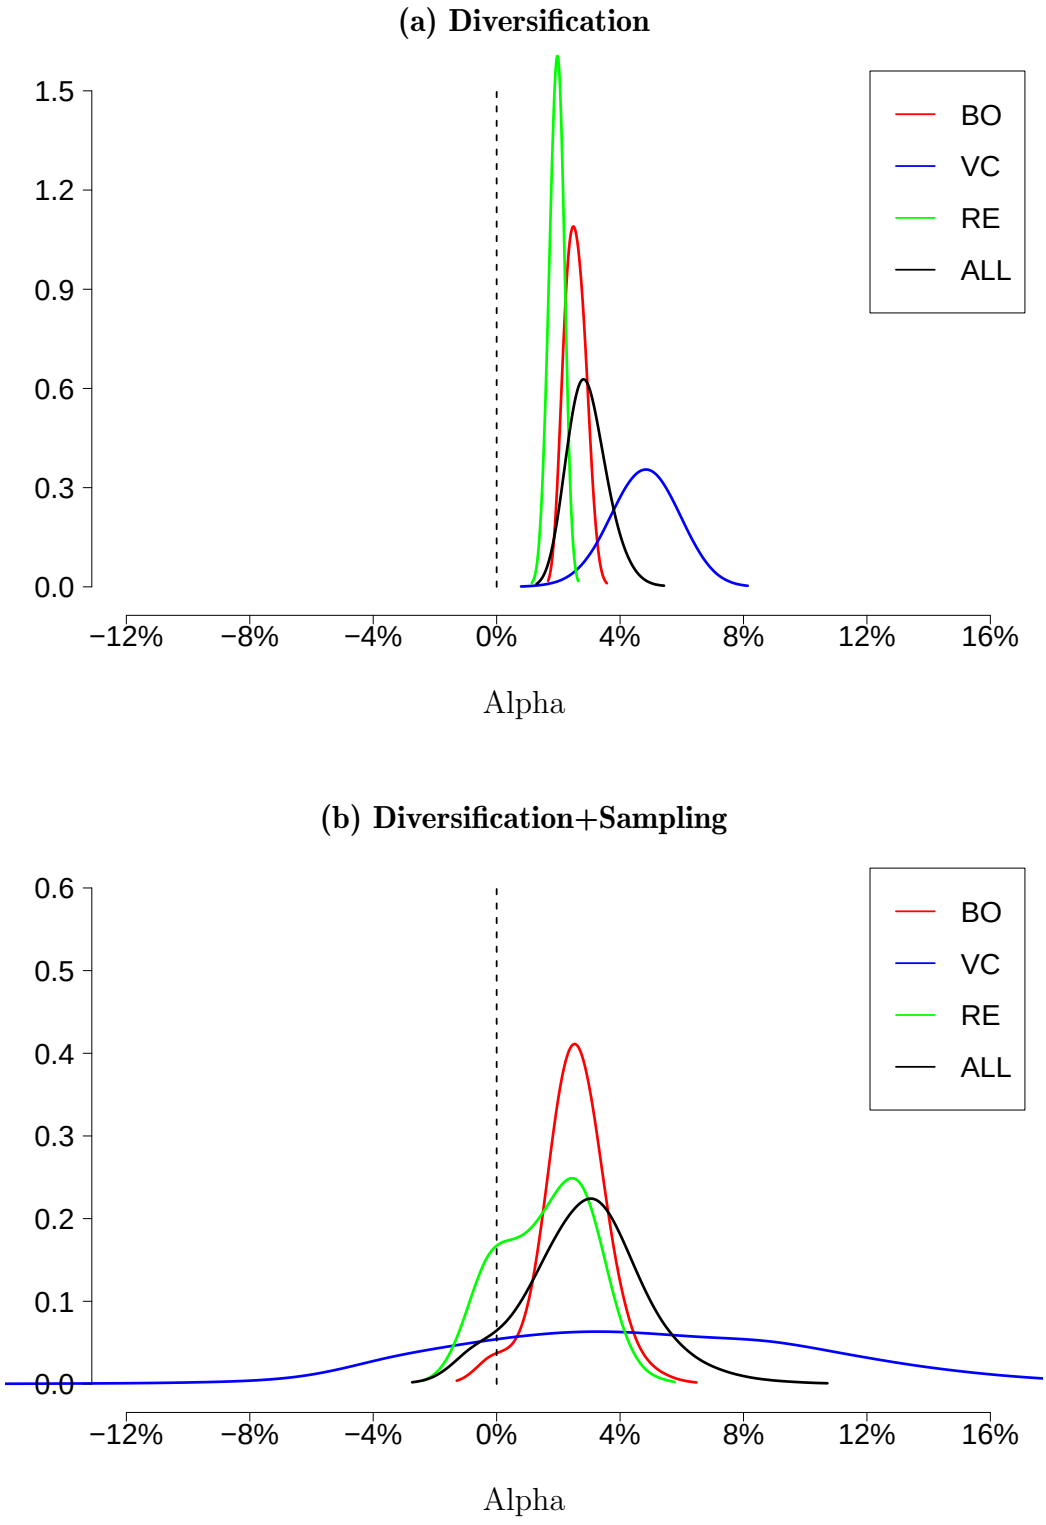

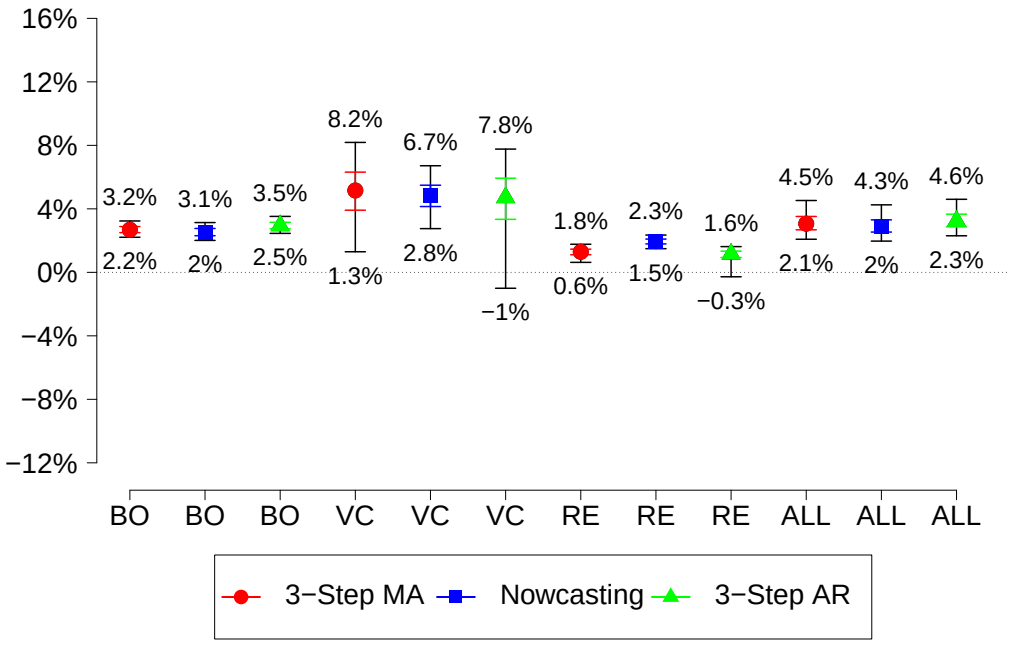

Figure 6
Private Capital Alpha: Smoothed Density Functions

This figure plots the smoothed density functions for the alpha of each private capital asset class we study: buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The results are based on 10,000 simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (see Section 2 for details on these simulations). All private capital returns use the nowcasted NAVs from Brown, Ghysels, and Gredil (2023) to correct for stale NAVs. Panel (a) accounts for the uncertainty associated with an LP that commits capital to only 9 funds each period. Panel (b) compounds the uncertainty associated with underdiversification and sampling variation. Subsection 2.2 provides data details and Subsection 3.3 provides a description of the results in this figure.

(a) Alpha 95% CI: Diversification

(b) Alpha 95% CI: Diversification+Sampling

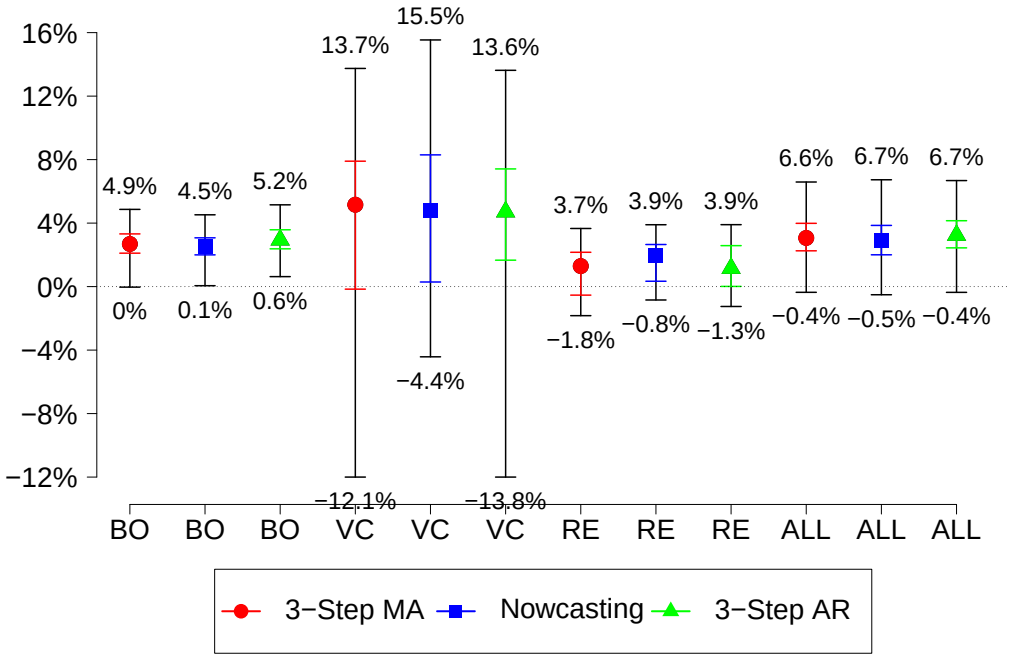

Figure 7
Alpha 95% Confidence Intervals: Alternative Methods to Deal with Stale NAVs

This figure plots the interquartile range and the 95% confidence interval for the alpha of each private capital asset class we study: buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The results are based on 10,000 simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (see Section 2 for details). The dots reflect the median alpha values across simulations for the given specification. The blue bars are for our baseline specification that uses nowcasted NAVs from Brown, Ghysels, and Gredil (2023) whereas the red and green bars rely on alternative methods to correct for stale NAVs. They are adaptations of the 3-step MA and AR unsmoothing processes of Couts, Gonçalves, and Rossi (2024) to our setting. Panel (a) accounts for the uncertainty associated with an LP that commits capital to only 9 funds each period. Panel (b) compounds the uncertainty associated with underdiversification and sampling variation. Subsection 2.2 provides data details and Subsection 4.1 provides a description of the results in this table.

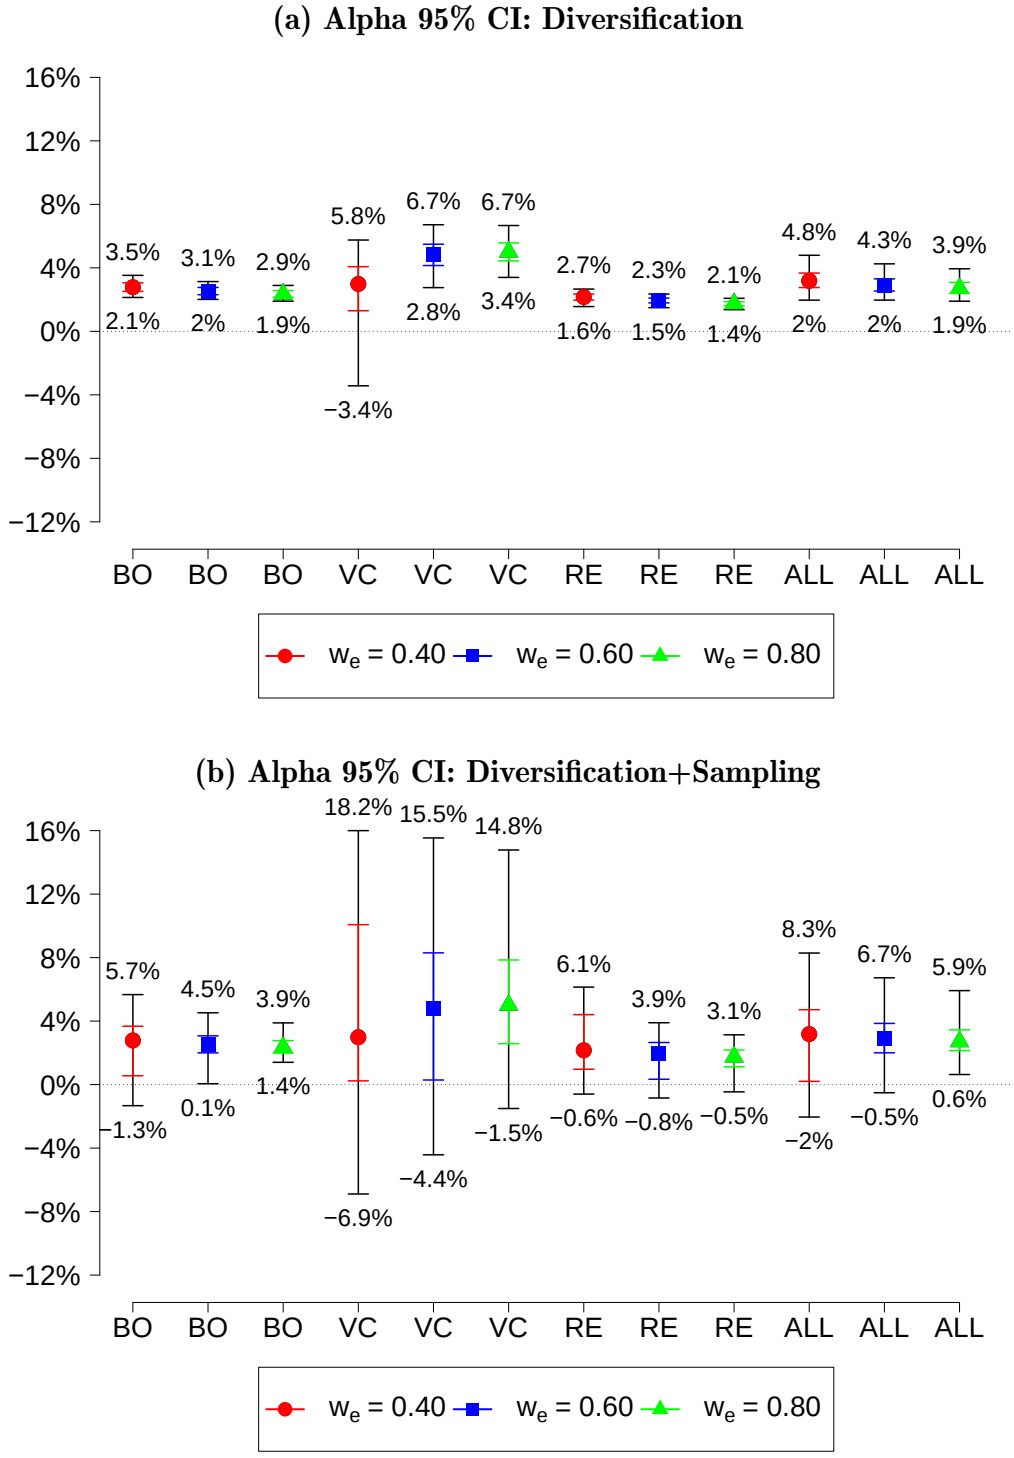

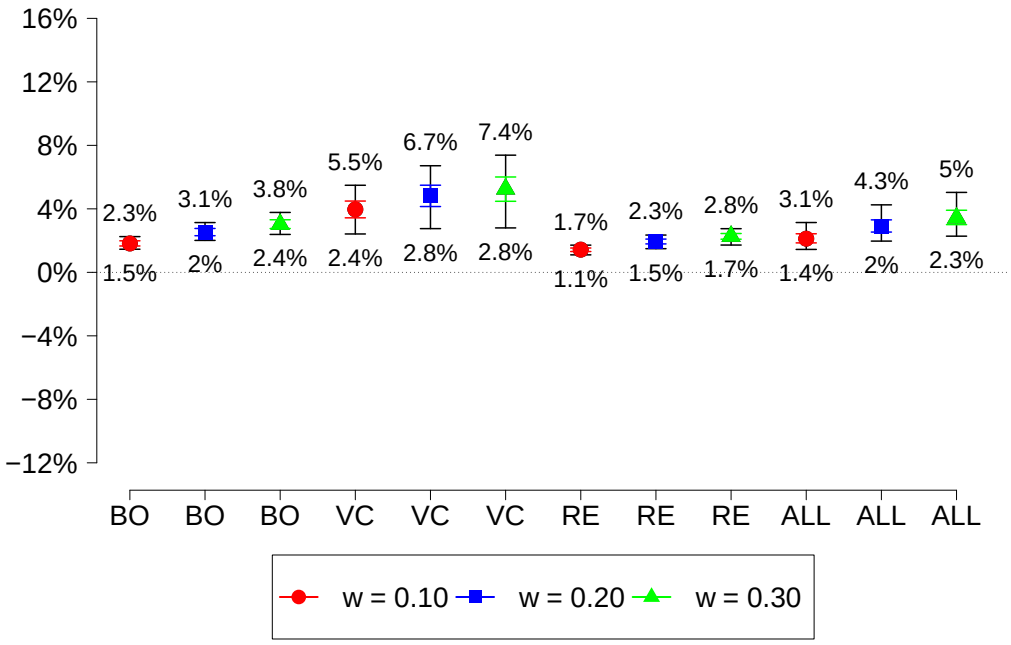

Figure 8
Alpha 95% Confidence Intervals: Alternative Public Market Portfolios

This figure plots the interquartile range and the 95% confidence interval for the alpha of each private capital asset class we study: buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The results are based on 10,000 simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (see Section 2 for details). The dots reflect the median alpha values across simulations for the given specification. The blue bars are for our baseline specification whereas the red and green bars are for specifications with alternative public equity allocations. All private capital returns use nowcasted NAVs from Brown, Ghysels, and Gredil (2023) to adjust for NAV smoothing. Panel (a) accounts for the uncertainty associated with an LP that commits capital to only 9 funds each period. Panel (b) compounds the uncertainty associated with underdiversification and sampling variation. Subsection 2.2 provides data details and Subsection 4.2 provides a description of the results in this table.

(a) Alpha 95% CI: Diversification

(b) Alpha 95% CI: Diversification+Sampling

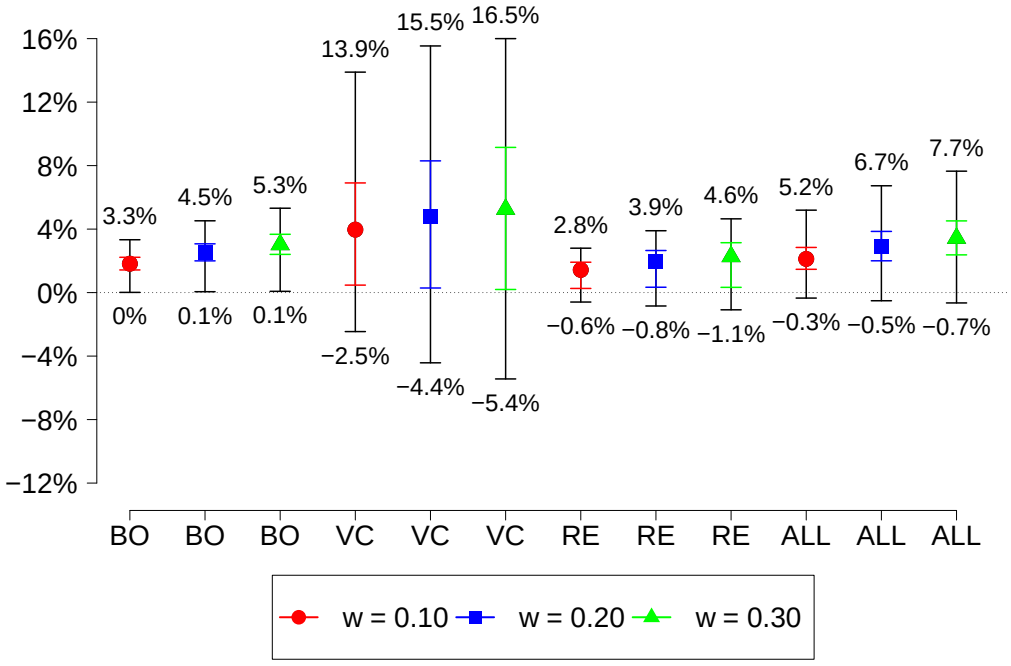

Figure 9
Alpha 95% Confidence Intervals: Alternative Target Allocations to Private Capital

This figure plots the interquartile range and the 95% confidence interval for the alpha of each private capital asset class we study: buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The results are based on 10,000 simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (see Section 2 for details). The dots reflect the median alpha values across simulations for the given specification. The blue bars are for our baseline specification whereas the red and green bars are for specifications with alternative private capital allocations. All private capital returns use nowcasted NAVs from Brown, Ghysels, and Gredil (2023) to adjust for NAV smoothing. Panel (a) accounts for the uncertainty associated with an LP that commits capital to only 9 funds each period. Panel (b) compounds the uncertainty associated with underdiversification and sampling variation. Subsection 2.2 provides data details and Subsection 4.3 provides a description of the results in this table.

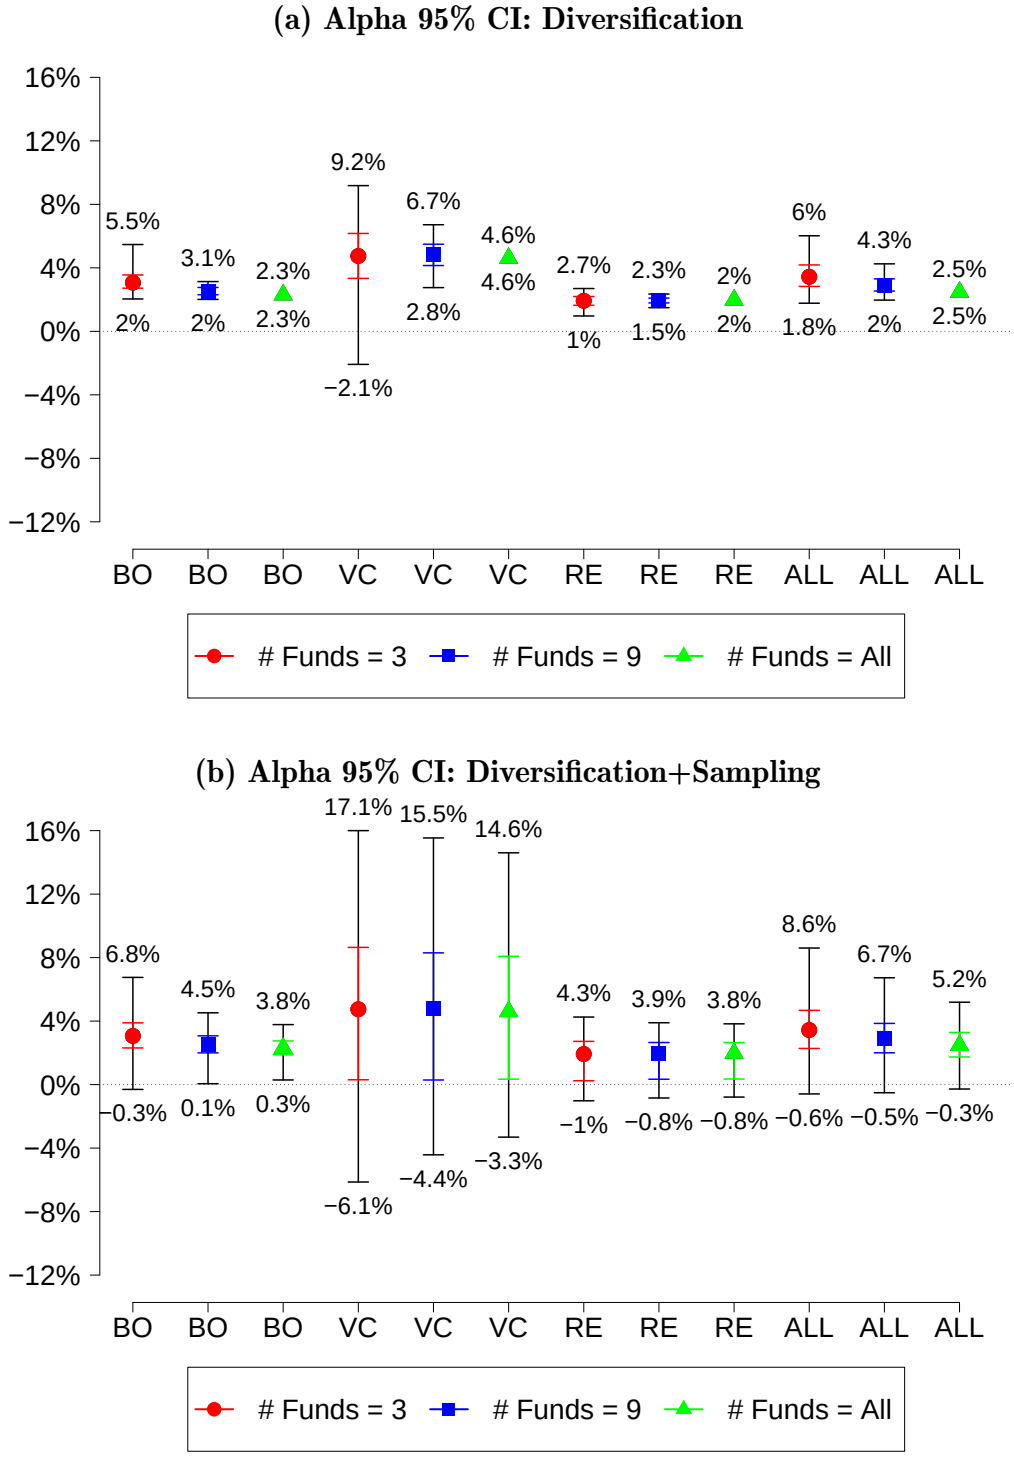

Figure 10
Alpha 95% Confidence Intervals: Alternative Levels of Private Capital Diversification

This figure plots the interquartile range and the 95% confidence interval for the alpha of each private capital asset class we study: buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The results are based on 10,000 simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (see Section 2 for details). The dots reflect the median alpha values across simulations for the given specification. The blue bars are for our baseline specification whereas the red and green bars are for specifications with alternative levels of diversification. All private capital returns use nowcasted NAVs from Brown, Ghysels, and Gredil (2023) to adjust for NAV smoothing. Panel (a) accounts for the uncertainty associated with an LP that commits capital to only 9 funds each period. Panel (b) compounds the uncertainty associated with underdiversification and sampling variation. Subsection 2.2 provides data details and Subsection 4.4 provides a description of the results in this table.

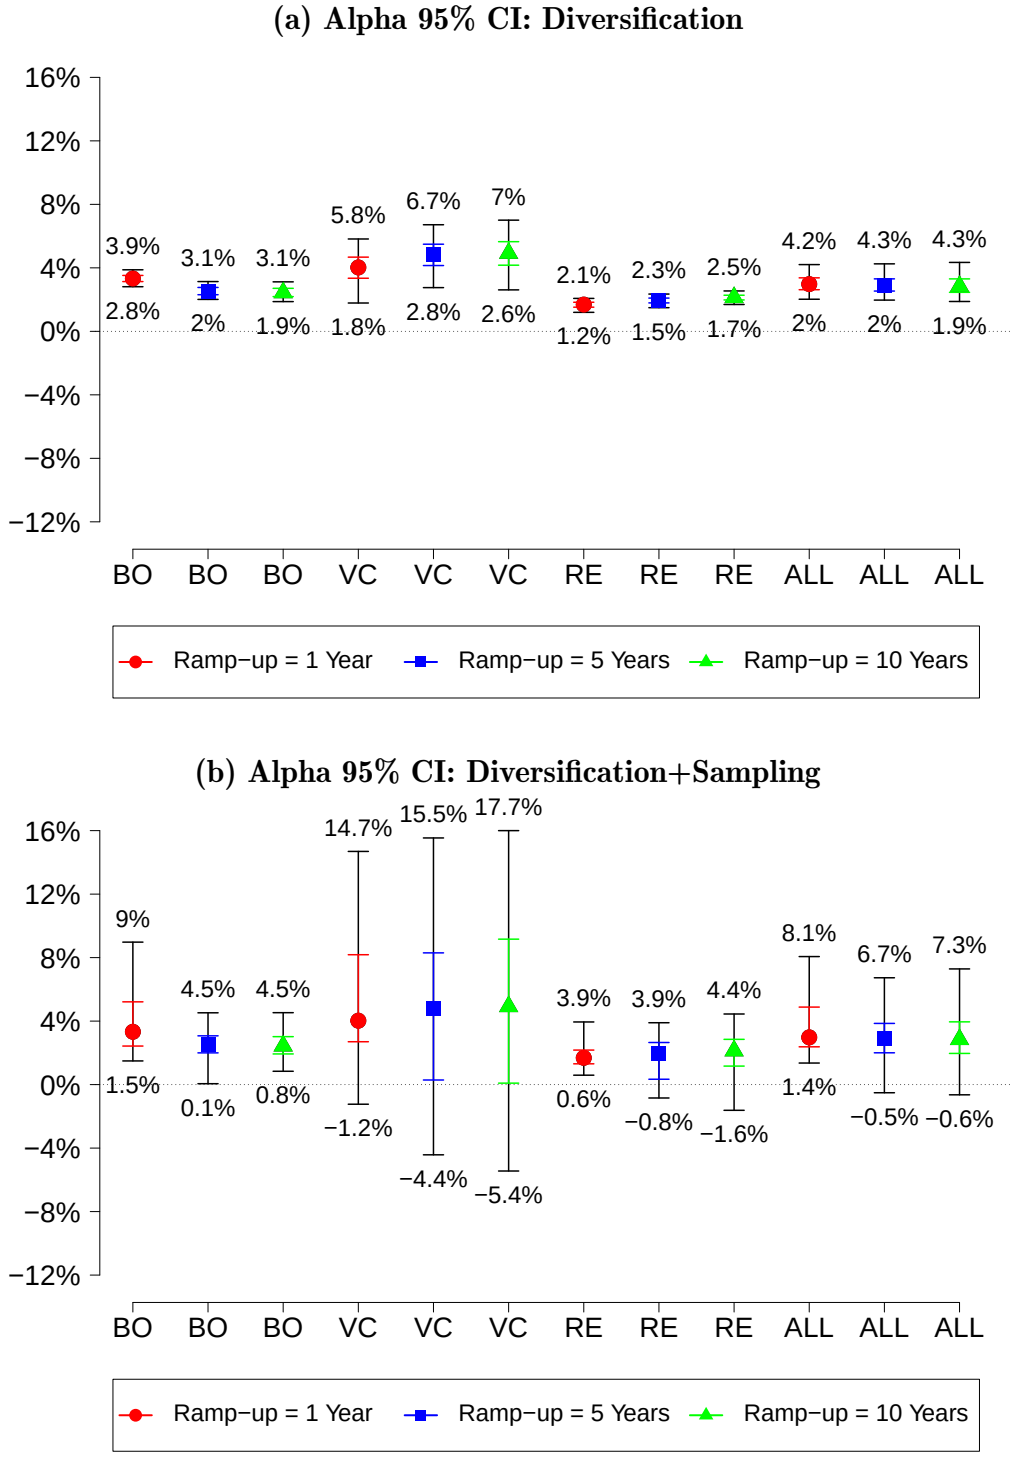

Figure 11
Alpha 95% Confidence Intervals: Alternative ramp-up Periods

This figure plots the interquartile range and the 95% confidence interval for the alpha of each private capital asset class we study: buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The results are based on 10,000 simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (see Section 2 for details). The dots reflect the median alpha values across simulations for the given specification. The blue bars are for our baseline specification whereas the red and green bars are for specifications with alternative ramp-up periods. All private capital returns use nowcasted NAVs from Brown, Ghysels, and Gredil (2023) to adjust for NAV smoothing. Panel (a) accounts for the uncertainty associated with an LP that commits capital to only 9 funds each period. Panel (b) compounds the uncertainty associated with underdiversification and sampling variation. Subsection 2.2 provides data details and Subsection 4.5 provides a description of the results in this table.

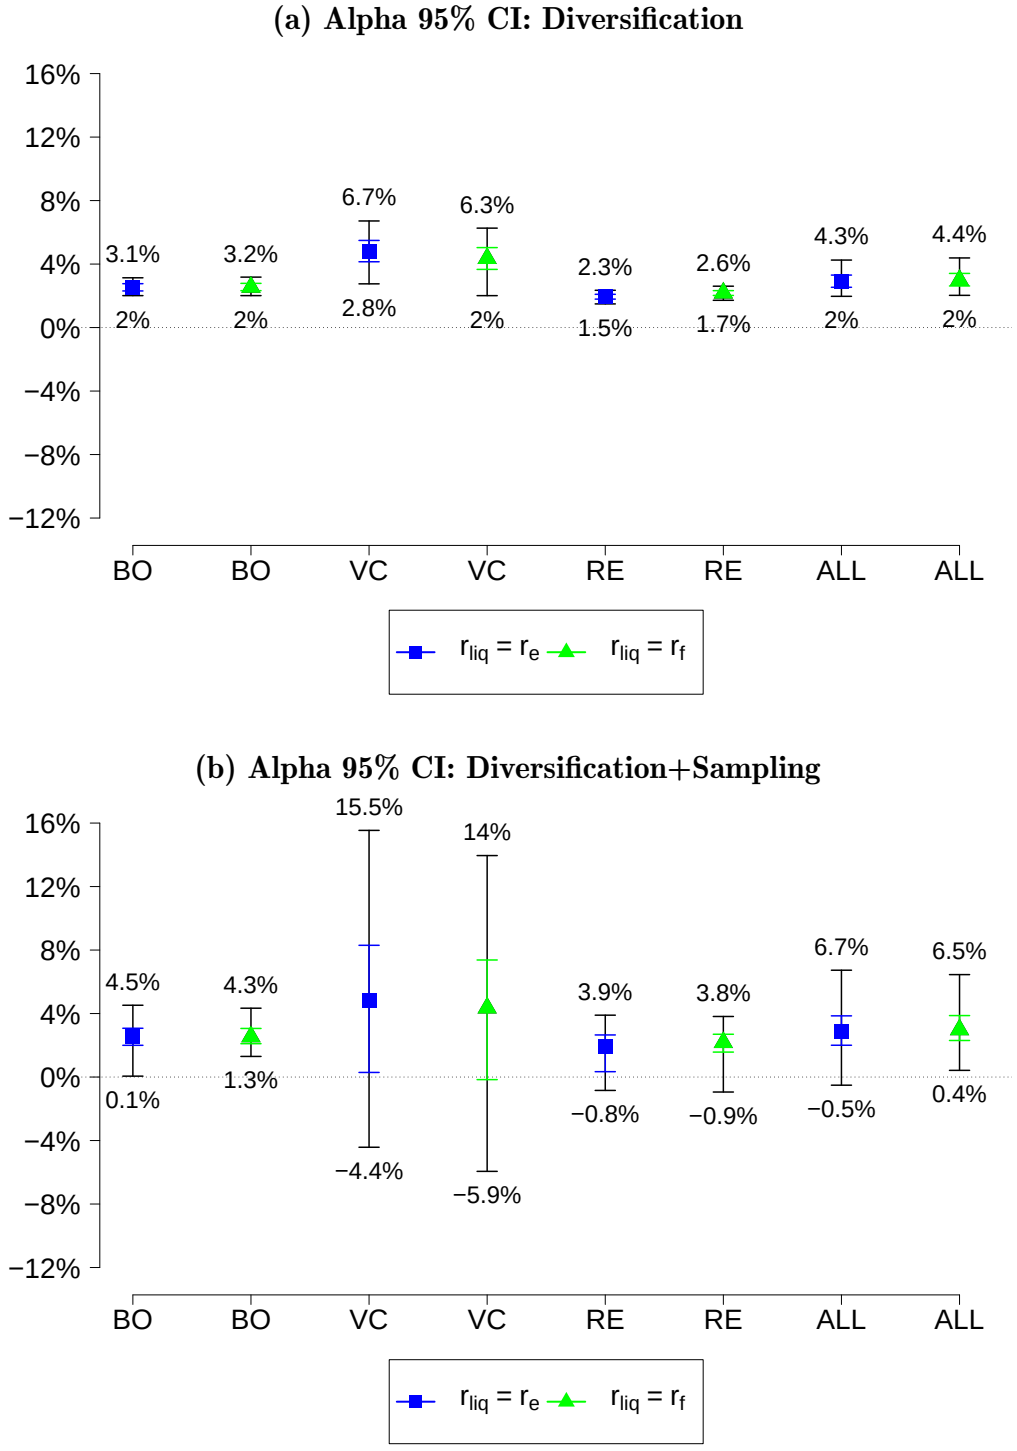

Figure 12
Alpha 95% Confidence Intervals: Alternative Liquid Asset

This figure plots the interquartile range and the 95% confidence interval for the alpha of each private capital asset class we study: buyout (BO), venture capital (VC), real estate (RE), and the three combined in a value-weighted manner (ALL). The results are based on 10,000 simulations that account for important considerations related to underdiversification, illiquidity, and LP portfolio allocations (see Section 2 for details). The dots reflect the median alpha values across simulations for the given specification. The blue bars are for our baseline specification whereas the green bars are for an alternative specification with Treasury bills as the liquid asset. All private capital returns use nowcasted NAVs from Brown, Ghysels, and Gredil (2023) to adjust for NAV smoothing. Panel (a) accounts for the uncertainty associated with an LP that commits capital to only 9 funds each period. Panel (b) compounds the uncertainty associated with underdiversification and sampling variation. Subsection 2.2 provides data details and Subsection 4.6 provides a description of the results in this table.

D.3 3-Step AR Unsmoothed NAVs IA.12

A Derivation of the Alpha Expression

This section derives Equation 2 in the main text.

Equation 6.6.17 in Campbell, Lo, and MacKinlay (1997) (originally derived in Gibbons, Ross, and Shanken (1989)) shows that the the factor model

$$r_t^* \ = \alpha^* \ + \ \beta^* \cdot r_{p,t}^* \ + \ \epsilon_t^* \tag{IA.1}$$

implies

$$\frac{\alpha^{*2}}{\sigma^2[\epsilon_t^*]} \ = \mathbb{SR}[r_{pp,t}^*]^2 \ - \ \mathbb{SR}[r_{p,t}^*]^2 \tag{IA.2}$$

where $r_{pp,t}^* = w^* \cdot r_t^* + (1 - w^*) \cdot r_{p,t}^*$ represents the ex-post maximum Sharpe ratio portfolio that can be formed with $r_{p,t}^*$ and r_t^*.

Isolating α^*, we have

$$|\alpha^*| \ = \sigma[\epsilon_t^*] \cdot \sqrt{\left(\mathbb{SR}[r_{pp,t}^*]^2 \ - \ \mathbb{SR}[r_{p,t}^*]^2\right)} \tag{IA.3}$$

Now, note that the a positive (negative) α^* implies a positive (negative) w^* and thus Equation IA.3 simplifies to

$$\alpha^* \ = sign(w^*) \cdot \sigma[\epsilon_t^*] \cdot \sqrt{\left(\mathbb{SR}[r_{pp,t}^*]^2 \ - \ \mathbb{SR}[r_{p,t}^*]^2\right)} \tag{IA.4}$$

Finally, since $r_{pp,t}^*$ is the ex-post maximum Sharpe ratio portfolio that can be formed with $r_{p,t}^*$ and r_t^*, we have that $\mathbb{SR}[r_{pp,t}^*]^2 \ \geq \ \mathbb{SR}[r_{p,t}^*]^2$, and thus $\mathbb{SR}[r_{pp,t}^*]^2 - \mathbb{SR}[r_{p,t}^*]^2 = \left|\mathbb{SR}[r_{pp,t}^*]^2 - \mathbb{SR}[r_{p,t}^*]^2\right|$ so that Equation IA.4 can be written as

$$\alpha^* \ = sign(w^*) \cdot \sigma[r_t^*] \cdot \sqrt{\left|\mathbb{SR}[r_{pp,t}^*]^2 \ - \ \mathbb{SR}[r_{p,t}^*]^2\right|} \tag{IA.5}$$

which is Equation 2 in the main text.

Note also that $\sigma[\epsilon_t^*]$ can be directly written in terms of return moments. Specifically, the coefficient of determination of the factor model in Equation IA.1 is given by $\mathbb{C}or[r_t^*, r_{p,t}^*]^2 = 1 - \sigma^2[\epsilon_t^*]/\sigma^2[r_t^*]$, which implies

$$\sigma[\epsilon_t^*] \ = \sigma[r_t^*] \cdot \sqrt{1 - \mathbb{C}or[r_t^*, r_{p,t}^*]^2} \tag{IA.6}$$

B The Allocation of US Public Pension Funds

We obtain US public pension fund weights from the Center for Retirement Research (CRR) at Boston College. Specifically, we collect information on the dollar allocations across asset classes for each pension fund (from the "Detailed Investment Data" dataset). Then, we aggregate allocations across pension funds with non-missing AUM each year.

CRR provides information on allocations for a range of asset classes, many of which have zero weights for most pension funds. To create the aggregate allocations on our broad asset classes, we follow a procedure similar to Couts, Gonçalves, and Loudis (2024) and Couts et al. (2024). Specifically, we sum the allocations on narrower asset classes as follows (with asset class names as recorded in the CRR dataset):

1. **Fixed Income**: FIUS + FIExUS + FIOther + FICash + Cash
2. **Equities**: EQUS + EQExUS + EQOther
3. **Private Equity**: EQPrivate + PrivatePlacement + MLP
4. **Venture Capital**: No asset class (it is included within Private Equity)
5. **Real Estate**: RECore + REMisc + RENonCore + PrivRealEstate + REIT + RealAssets + RETriple
6. **Hedge Funds**: AbsRtrn + RelativeRtrn + RiskParity + CoveredCall + CreditOpp + DistrssedDebt + DistrssedLend + HedgeEQ + AltInflation + Hedge + MultiClass + OppDebt + OppEQ + Opp + GTAA
7. **Commodities**: Commod+Farm+NatResources+Timber
8. **Private Debt**: PrivateDebt
9. **Infrastructure**: Infrast

FIUS and EQUS reflect asset classes that are based on US investments, FIExUS and EQExUS reflect asset classes that are based on international investments, and FIOther and EQOther reflect asset classes that can potentially combine US and Ex US investments. We construct these six asset classes as follows:

1. **FIUS**: FIDomestic + FITIPS + FITreasury
2. **EQUS**: EQDomesticLarge + EQDomesticMisc + EQDomesticMid + EQDomesticSmall
3. **FIExUS**: FIEmerg + FIGlobal + FIIntl
4. **EQExUS**: EQIntlActv + EQIntlDev + EQGlobal + EQIntlMisc + EQIntlPass + EQIntlEmerg + EQGlobalGrowth
5. **FIOther**: FICore + FINonCore + FICorpBonds + FIValue + FIConv + FIAlt + FIFundsFunds + FIMisc + FIETI + FINominal + FIInvestGrd + FIBelowInvestGrd + FIHighYield + FILoans + PrivateDebt + FIMortgage + FIGIPS + FIOpp + FIStructured + ω_{FI}·MiscEQFI
6. **EQOther**: EQCore+EQLarge+EQMisc+EQMicro+EQSmall+EQOpportunistic+EQSocialResp + $(1-\omega_{\text{FI}})$·MiscEQFI

The ω_{FI} weight is equal to the allocation on FIUS+FIExUS+FIOther* dividend by the allocation on FIUS+FIExUS+FIOther*+EQUS+EQExUS+EQOther*, where FIOther* and EQOther* are the FIOther and EQOther asset classes with MiscEQFI set to zero (so that we do not need ω_{FI} to compute them).

Some of the narrower asset classes have missing weights in some years (which we set to zero). However, this issue is not major, with the aggregate dollar allocation of pension funds (with non-missing AUM) summing to 92.8% of the aggregate pension fund AUM in 2001 (the first year of the dataset), with this number increasing to 98.3% by 2006 and to 99.8% by 2022 (the last year in our dataset).

The weights in Figure 3(a) are calculated as a fraction of the total aggregate non-missing weight for the given year. The weights in Figure 3(b) are calculated as a fraction of the weight allocated to the five asset classes we study (Fixed Income, Equities, Private Equity, Venture Capital, and Real Estate).

C Calibrating Annual Contribution to Private Capital

We select the contribution rate, c, such that the median w_t matches the target $w = 0.20$ after the first ten years of simulation (because in the first years w_t is mechanically lower than w since $w_0 = 0$). The matching of the median w_t to w is done in an initial simulation without underdiversification (i.e., a simulation in which the LP invests in all funds of the given asset class raised in each vintage year). This approach ensures that the c value does not vary across the simulations. The details of this calibration process are provided below.

Suppose we have an initial guess ($c^{(0)}$) for the contribution rate. We perform the fully diversified simulation and, at the end, update the contribution rate using $c^{(1)} = \frac{w}{median(w_t)} \cdot c^{(0)}$, where the $median(w_t)$ is calculating after burning the first ten years of simulation. We repeat this process with $c^{(k+1)} = \frac{w}{median(w_t)} \cdot c^{(k)}$ until $c^{(k+1)}$ converges to $c^{(k)}$. We set $c^{(0)}$ to the steady state contribution rate, c^{ss}, obtained as described below.

An annual commitment of c^{ss} yields a steady state allocation of $w = \lambda \cdot c^{ss}$ so that we can determine the target steady state commitment, $c^{ss} = (1/\lambda) \cdot w$, for any given w by estimating the allocation multiplier λ. To calibrate λ, substitute $\pi^{(v)}$ (Equation 7) into w_t (Equation 8) to obtain

$$w_t = c^{ss} \cdot \sum_{v=y_t-20}^{v=y_t} \frac{\text{AUM}^{(v-1)}}{\text{AUM}_t} \cdot \frac{\text{NAV}_t^{(v)}}{\text{Size}^{(v)}} \tag{IA.7}$$

Then, letting g_v represent the annual growth in the LP's AUM (i.e., $\text{AUM}^{(v)} = (1 + g_v) \cdot \text{AUM}^{(v-1)}$), Equation IA.7 (at the last quarter of each year) can be written as

$$w_t = c^{ss} \cdot \sum_{v=y_t-20}^{v=y_t} \frac{1}{\prod_{j=v}^{j=y_t}(1 + g_j)} \cdot \frac{\text{NAV}_t^{(v)}}{\text{Size}^{(v)}} \tag{IA.8}$$

so that in steady state we have

$$w = c^{ss} \cdot \sum_{h=0}^{h=20} \frac{\text{NAVf}^{(h)}}{(1+g)^{h+1}} \tag{IA.9}$$

where g is the LP's AUM steady state annual growth and $\text{NAVf}^{(h)} = \text{NAV}_t^{(v)}/\text{Size}^{(v)}$ is

the steady state NAV as a fraction of fund size, which is a function only of the time since inception, $h = y_t - v$.

Combining Equation IA.9 with $w = \lambda \cdot c^{ss}$ implies the allocation multiplier

$$\lambda = \sum_{h=0}^{h=20} \frac{\text{NAVf}^{(h)}}{(1+g)^{h+1}} \tag{IA.10}$$

Figure IA.1(a) plots the total NAV of funds in each asset class relative to their size averaged over time, with the x-axis reflecting the time since the fund's inception year (i.e., the figure displays $\text{NAVf}^{(h)}$ for a strategy in which I_v includes all funds with vintage year v). As the figure shows, only a small fraction of the total commitment is called in the inception year, resulting in a relatively small $\text{NAVf}^{(0)}$ (between 10% and 30%). The total $\text{NAVf}^{(h)}$ grows in the subsequent years through asset returns and capital calls, reaching its peak in $h = 3$ to 5 years depending on the asset class. Then, the $\text{NAVf}^{(h)}$ tends to decline over the subsequent years since distributions outpace capital calls.[IA.1] By year $h = 20$, all funds have been liquidated and thus we have $\text{NAVf}^{(h)} = 0$ for $h \geq 20$.

Figure IA.1(b) displays, for each asset class, λ as a function of g based on Equation IA.10 by combining the $\text{NAVf}^{(h)}$ estimates in Figure 2(a) with different g values. The allocation multiplier tends to be higher for venture capital funds relative to buyout and real estate funds. In our baseline analysis, we use $g = 10\%$ to obtain $c^{(0)} = c^{ss}$, which implies $\lambda_{BO} = 3.98$, $\lambda_{VC} = 5.67$, and $\lambda_{RE} = 3.68$. Since $c = (1/\lambda) \times 20\%$, we then rely on the annual steady state commitment rates $c^{ss}_{BO} = 5.0\%$, $c^{ss}_{VC} = 3.5\%$, and $c^{ss}_{RE} = 5.4\%$ for our BO, VC, and RE portfolios, respectively. These commitment rates imply the private capital allocation target of $w = 20\%$ in steady state regardless of the asset class under analysis (under a 10% AUM growth).

As explained in Subsection 2.3.5, we make some modifications in the capital commitment process for the $r_{pp,t}$ version in which r_t contains BO, VC, and RE jointly (which we refer to as ALL). We assume that the LP still has a target weight of $w = 0.20$ for private capital

[IA.1] Typically, capital must be called within the first 5 years of a fund's life though exceptions can be made by for certain types of investments such as add-ons. Also, LPs can grant extensions.

but distributes its commitment each vintage year across asset classes in a value-weighted manner (i.e., based on the total capital being raised by each asset class in each vintage year). Specifically, the commitment (as a fraction of AUM) to asset class k associated with the vintage year v is $c_{k,v} = \phi_{k,v} \cdot \varphi_k \cdot c$, where c is the commitment parameter, the $\phi_{k,v} = \text{Size}_k^{(v)}/(\text{Size}_{\text{BO}}^{(v)} + \text{Size}_{\text{VC}}^{(v)} + \text{Size}_{\text{RE}}^{(v)})$ values are proportional to the capital being raised by each asset class, and the $\varphi_k = c_k^{ss}/(c_{\text{BO}}^{ss} + c_{\text{VC}}^{ss} + c_{\text{RE}}^{ss})$ values are proportional to the steady state commitment parameters. As above, c is chosen such that the median w_t matches the target $w = 0.20$ after the first ten years of simulation (in this case, $c^{(0)} = c_{\text{BO}}^{ss} + c_{\text{VC}}^{ss} + c_{\text{RE}}^{ss}$). Moreover, the LP continues to invest in 9 funds randomly, but requires 3 funds in each asset class, with commitments being value-weighted within each asset class.

D Dealing with Stale NAVs

As discussed in Subsection 2.3.6, illiquidity and incentive considerations can lead the reported NAVs to be stale, which in turn leads to understated risk and overstated risk-adjusted performance (see the discussions in Getmansky, Lo, and Makarov (2004) and Couts, Gonçalves, and Rossi (2024)). To highlight this issue, Figure IA.2 provides return autocorrelations for the public equity index as well as indices on each of the private capital asset classes we study. The key finding is that private capital asset classes have much higher return autocorrelations than public equity, which is a symptom of stale NAVs.

Given the discussion above, our baseline analysis uses the nowcasted NAVs from Brown, Ghysels, and Gredil (2023) when constructing the private capital returns in Equation 9. Moreover, in the sensitivity analysis of Subsection 4.1, we consider two alternative methods to deal with the same issue. They are both based on an adaptation of the 3-step unsmoothing method of Couts, Gonçalves, and Rossi (2024). The key difference between the two unsmoothing methods we consider is that the 3-step moving average (MA) unsmoothing method keeps the unsmoothing process as flexible as possible at the cost of a relatively large number of unsmoothing parameters (nesting the method in Getmansky, Lo, and Makarov (2004)) whereas the 3-step autoregressive (AR) unsmoothing method keeps the number of parameters small through a parametrization that is reasonable, but potentially mispecified (nesting the method in Geltner (1991, 1993)). All details about our use of nowcasted NAVs as well as return unsmoothing are provided below.

D.1 Nowcasted NAVs

We obtain each fund-quarter nowcasted NAV ($NCNAV$) directly from the M24 version of the Brown, Ghysels, and Gredil (2023) dataset (which has $NCNAV$ updated until Q42022). For the fund-quarters in which the $NCNAV$ is missing, we use the reported NAV ($RPNAV$). For fund-quarters with $NCNAV < RPNAV/100$, we set $NCNAV = RPNAV/100$. Similarly, for fund-quarters with $NCNAV > RPNAV \cdot 100$, we set $NCNAV = RPNAV \cdot 100$. Finally,

if $|log(PME_{NC})| > 0.15$, then we set $NCNAV = RPNAV$ as the error on the nowcasting process is likely too high.[IA.2]

Figures IA.3(b) to IA.5(b) provide the return autocorrelations for BO, VC, and RE (respectively) using aggregate returns constructed from nowcasted NAVs ($R_t = (NCNAV_t + CF_t)/NCVAV_{t-1}$). As it is clear from the figures, nowcasted returns tend to have much lower autocorrelations than reported returns. This indicates that nowcasted NAVs are better measures of the true NAVs. Nevertheless, there is still some remaining relatively high autocorrelations for VC and RE, which could be spurious. The unsmoothing methods of the next two subsections deal with this issue (and, as shown in Subsection 4.1, lead to alpha results that are similar to our baseline ones).

D.2 3-Step MA Unsmoothed NAVs

Let's start by introducing some notation. Economic (or unsmoothed) fund-level returns are given given by $R_{j,t} = \mu_j + \eta_{j,t}$ where $\eta_{j,t} \sim \mathcal{N}(0, \sigma_\eta)$. Then, we define aggregate returns as $\overline{R}_t \equiv (1/J) \cdot \sum_{j=1}^{J} R_{j,t} = \overline{\mu} + \overline{\eta}_t$ and excess returns as $\widetilde{R}_t \equiv R_{j,t} - \overline{R}_t = \widetilde{\mu}_j + \widetilde{\eta}_{j,t}$. Moreover, we note that $\widetilde{\eta}_{j,t}$ and $\overline{\eta}_t$ can be correlated over time.

The 3-step MA unsmoothing method of Couts, Gonçalves, and Rossi (2024) (CGR) assumes that the reported (or observed) return of fund j at time t follows (see CGR for the economic motivation)

$$\begin{aligned} R^o_{j,t} &= \sum_{h=0}^{H} \phi_j^{(h)} \cdot \widetilde{R}_{j,t-h} + \sum_{h=0}^{H} \pi_j^{(h)} \cdot \overline{R}_{t-h} \\ &= \mu_j + \sum_{h=0}^{H} \phi_j^{(h)} \cdot \widetilde{\eta}_{j,t-h} + \sum_{h=0}^{H} \pi_j^{(h)} \cdot \overline{\eta}_{t-h} \end{aligned} \tag{IA.11}$$

[IA.2] PME_{NC} reflects the PME of the fund constructed using the methodology in Kaplan and Schoar (2005), but replacing the returns on the public market benchmark with the nowcasted fund returns. If the nowcasted fund returns were identical to the true (unobserved) fund returns, then we would have $PME_{NC} = 1$ (and $|log(PME_{NC})| = 0$). In cases in which the fund is not fully resolved, we use the $RPNAV$ (instead of $NCNAV$) as the last valuation of the fund when calculating PME_{NC}. This approach ensures the nowcasting method is not used in the cash flow part of the PME calculation (only the discounting part).

where $\sum_{h=0}^{H} \phi_j^{(h)} = \sum_{h=0}^{H} \pi_j^{(h)} = 1$. This process implies the aggregate reported returns

$$\begin{aligned} \overline{R}_t^o &= \sum_{h=0}^{H} \pi^{(h)} \cdot \overline{R}_{t-h} \\ &= \overline{\mu} + \sum_{h=0}^{H} \pi^{(h)} \cdot \overline{\eta}_{t-h} \end{aligned} \tag{IA.12}$$

where $\sum_{h=0}^{H} \pi^{(h)} = 1$, and the fund-level excess reported returns

$$\begin{aligned} \widetilde{R}_{j,t}^o &= \sum_{h=0}^{H} \phi_j^{(h)} \cdot \widetilde{R}_{j,t-h} + \sum_{h=0}^{H} \psi_j^{(h)} \cdot \overline{R}_{t-h} \\ &= \widetilde{\mu}_j + \sum_{h=0}^{H} \phi_j^{(h)} \cdot \widetilde{\eta}_{j,t-h} + \sum_{h=0}^{H} \psi_j^{(h)} \cdot \overline{\eta}_{t-h} \end{aligned} \tag{IA.13}$$

where $\psi_j^{(h)} = \pi_j^{(h)} - \pi^{(h)}$ so that $\sum_{h=0}^{H} \psi_j^{(h)} = 0$.

CGR performs their unsmoothing process in three steps (hence the name 3-step method). First, they estimate $\overline{\eta}_t$ by Maximum Likelihood Estimation (MLE) applied to Equation IA.12 (which is an MA(H) process). Second, they estimate $\widetilde{\eta}_{j,t}$ by MLE applied to Equation IA.13 (which is an MA(H) process with exogenous variable $\overline{\eta}_t$). Third, they recover unsmoothed returns from $R_{j,t} = \mu_j + \widetilde{\eta}_{j,t} + \overline{\eta}_t$.

We adapt their method to our setting by allowing the unsmoothing process for the aggregate return to depend directly on external factors (f_t), which in our empirical analysis are the (demeaned) returns on the public equity and bond portfolios. Specifically, we assume $\widetilde{R}_t^o$ still follows Equation IA.13, but the smoothing process for $\overline{R}_t^o$ (Equation IA.12) is replaced with a slightly more general equation:[IA.3]

$$\begin{aligned} \overline{R}_t^o &= \sum_{h=0}^{H} \pi^{(h)} \cdot \overline{R}_{t-h} + \sum_{h=0}^{H} \theta^{(h)} \cdot \beta' f_{t-h} \\ &= \overline{\mu} + \sum_{h=0}^{H} \pi^{(h)} \cdot \xi_{t-h} + \sum_{h=0}^{H} \beta^{(h)'} f_{t-h} \end{aligned} \tag{IA.14}$$

[IA.3] Note that if $\theta^{(h)} = 0$ (i.e., the factors in f_t only affect the smoothing process through $\overline{R}_t$), then we recover exactly Equation IA.12 from the standard 3-step MA unsmoothing method.

where $\overline{\eta}_t = \beta' f_t + \xi_t$. Moreover, we have $\sum_{h=0}^{H} \pi^{(h)} = 1$ and $\sum_{h=0}^{H} \theta^{(h)} = 0$ to ensure information is properly incorporated into prices in the long-run. These restrictions then imply $\sum_{h=0}^{H} \beta^{(h)} = \sum_{h=0}^{H} \theta^{(h)} \cdot \beta' = \beta$.

We estimate our adapted 3-step MA unsmoothing model as follows. First, we estimate $\overline{\eta}_t = \beta' f_t + \xi_t$ with $f_t = (R_{e,t} - \mu_e, R_{b,t} - \mu_b)$ by MLE on Equation IA.14 (which is an MA(H) process with the f_{t-h} vectors as exogenous variables). Similar to CGR, this first step is estimated using the entire history of $\overline{R}_t^o$ so that it is estimated once for each private capital asset class rather than separately for each fund. Second, we estimate $\widetilde{\eta}_{j,t}$ by MLE applied to Equation IA.13 (which is an MA(H) process with exogenous variable $\overline{\eta}_t$). This second step is done separately for each fund and follows the CGR procedure.[IA.4] The third step simply recovers unsmoothed returns from $R_{j,t} = \mu_j + \widetilde{\eta}_{j,t} + \overline{\eta}_t$, as in CGR.

CGR fix H in their main analysis and also explore an alternative specification in which H is selected using the Akaike Information Criterion (AIC). Since our main analysis has three different private capital asset classes (which likely have different H values), our main analysis directly relies on the AIC to select H, which is applied separately for each private capital asset class in the first step of the estimation process. The values of H selected by the AIC (between 0 and 8 quarters) are 2 quarters for BO, 3 quarters for VC, and 7 quarters for RE.

After obtaining fund-level unsmoothed returns, $R_{j,t}$, we construct unsmoothed NAVs ($UNNAV$) as follows. We start by setting $UNNAV_{j,t} = RPNAV_{j,t}$. Then, we recursively apply $UNNAV_{j,t+h} = max\{R_{j,t+h} \cdot UNNAV_{j,t+h-1} - CF_{j,t+h}, 0\}$. One challenge is that fund-level returns (reported and unsmoothed) can be very extreme in periods over which NAV is low relative to the total size of the fund (which tend to happen in the very beginning and end of a fund's life). To address this issue, we only obtain $R_{j,t}$ (and thus calculate $UNNAV_{j,t}$) for the period starting in the first quarter with two consecutive quarters of $RPNAV/Size > 0.05$ and ending in the first quarter (after at least 5 years) in which $RPNAV/Size \leq 0.05$ (or

[IA.4] In the second step (of unsmoothing excess fund-level returns), we require the given fund to have more than twenty quarters (i.e., five years) of return data with all gross returns being between 0 and 2 (i.e., between -100% and 100%). Otherwise, we set $\widetilde{\eta}_{j,t} = \widetilde{R}^o_{j,t}$.

one quarter before $RPNAV/Size = 0$ if that happens earlier). For other quarters, we rely on $UNNAV_{j,t} = NAV_{j,t}$.

Figures IA.3(c) to IA.5(c) provide the return autocorrelations for BO, VC, and RE (respectively) using aggregate returns constructed from 3-step MA unsmoothed NAVs. As it is clear from the figures, unsmoothed returns have much lower autocorrelation than reported returns (and also than nowcasted returns). This indicates that 3-step MA unsmoothed NAVs go a long way in solving the remaining autocorrelation issue with nowcasted NAVs. Yet, as shown in Subsection 4.1, the alpha results using 3-step MA unsmoothed NAVs are very similar to the alpha results using nowcasted NAVs.

D.3 3-Step AR Unsmoothed NAVs

Similar to our 3-step MA unsmoothing process, we adapt the 3-step AR unsmoothing method in CGR to our setting by allowing the unsmoothing process for the aggregate return to depend directly on external factors (f_t), which in our empirical analysis are the (demeaned) returns on the public equity and bond portfolios. Specifically, we assume that[IA.5]

$$\begin{aligned}\widetilde{R}^o_{j,t} &= \phi^{(0)}_j \cdot \widetilde{R}_{j,t} + \sum_{h=1}^{H} \phi^{(h)}_j \cdot \widetilde{R}^o_{j,t-h} + \psi^{(0)}_j \cdot \overline{R}_t + \sum_{h=1}^{H} \psi^{(h)}_j \cdot \overline{R}^o_{t-h} \\ &= \widetilde{\mu}_j + \sum_{h=1}^{H} \phi^{(h)}_j \cdot \widetilde{R}^o_{j,t-h} + \sum_{h=1}^{H} \psi^{(h)}_j \cdot \overline{R}^o_{t-h} + \underbrace{\phi^{(0)}_j \cdot \widetilde{\eta}_{j,t} + \psi^{(0)}_j \cdot \overline{\eta}_t}_{\varepsilon_{j,t}} \end{aligned} \tag{IA.15}$$

where $\sum_{h=0}^{H} \phi^{(h)}_j = 1$ and $\sum_{h=0}^{H} \psi^{(h)}_j = 0$, and that

$$\begin{aligned}\overline{R}^o_t &= \pi^{(0)} \cdot \overline{R}_t + \sum_{h=1}^{H} \pi^{(h)} \cdot \overline{R}^o_{t-h} + \theta^{(0)} \cdot \beta' f_t + \sum_{h=1}^{H} \theta^{(h)} \cdot \beta' f^o_{t-h} \\ &= \overline{\mu} + \sum_{h=1}^{H} \pi^{(h)} \cdot \overline{R}^o_{t-h} + \sum_{h=1}^{H} \beta^{(h)\prime} f^o_{t-h} + \underbrace{\pi^{(0)} \cdot \overline{\eta}_t + \theta^{(0)} \cdot \beta' f_t}_{\varepsilon_t} \end{aligned} \tag{IA.16}$$

[IA.5] Note that the excess return smoothing process in Equation IA.15 is the same as in CGR and the aggregate return smoothing process in Equation IA.16 is a slight generalization that would reduce to the aggregate return smoothing process of CGR if $\theta^{(h)} = 0$.

where $\sum_{h=0}^{H} \pi^{(h)} = 1$ and $\sum_{h=0}^{H} \theta^{(h)} = 0$. The parameter restrictions then imply $\phi_j^{(0)} = 1 - \sum_{h=1}^{H} \phi_j^{(h)}$, $\sum_{h=0}^{H} \psi_j^{(h)} = -\psi_j^{(0)}$, $\pi^{(0)} = 1 - \sum_{h=1}^{H} \pi^{(h)}$, and $\sum_{h=1}^{H} \beta^{(h)} = \sum_{h=1}^{H} \theta^{(h)} \cdot \beta' = -\theta^{(0)} \cdot \beta'$.

As in the 3-step MA unsmoothing process, we have $\overline{\eta}_t = \beta' f_t + \xi_t$. However, differently from the 3-step MA unsmoothing process, we also need $f_t^o = \sum_{h=1}^{H} \rho^{(h)} \cdot f_{t-h}^o + f_t$. The presence of f_t^o leads to a more complicated MLE (because we need to estimate $\rho^{(h)}$), which we simplify below by treating it as a sequence of simpler MLEs.

We estimate our adapted 3-step AR unsmoothing model as follows. First, we estimate $\overline{\eta}_t = \beta' f_t + \xi_t$ with $f_t = (R_{e,t} - \mu_e, R_{b,t} - \mu_b)$ by (quasi) MLE on Equation IA.16.[IA.6] Note that we use the residuals to get $\overline{\eta}_t = (\varepsilon_t - \theta^{(0)} \cdot \beta' f_t)/\pi^{(0)} = (\varepsilon_t + \sum_{h=1}^{H} \beta^{(h)} f_t)/(1 - \sum_{h=1}^{H} \pi^{(h)})$. As with the 3-step MA unsmoothing method, this first step is estimated using the entire history of $\overline{R}_t^o$ so that it is estimated once for each private capital asset class rather than separately for each fund. Second, we estimate $\widetilde{\eta}_{j,t}$ by MLE applied to Equation IA.15 (which is an AR(H) process with exogenous variables $\overline{R}_{t-h}^o$). This second step is done separately for each fund and applies the same filters as in our 3-step MA unsmoothing process. Note that we use the residuals to get $\widetilde{\eta}_t = (\varepsilon_{j,t} - \psi_j^{(0)} \cdot \overline{\eta}_t)/\phi_j^{(0)} = (\varepsilon_{j,t} + \sum_{h=1}^{H} \psi_j^{(h)} \cdot \overline{\eta}_t)/(1 - \sum_{h=1}^{H} \phi^{(h)})$. The third step simply recovers unsmoothed returns from $R_{j,t} = \mu_j + \widetilde{\eta}_{j,t} + \overline{\eta}_t$, as in CGR.

We still use the AIC to select H, but explore only $H = 0, 1, 2$ given that (i) the 3-step AR unsmoothing method above is more complex to estimate and (ii) AR processes account for long-run autocorrelation even with low H values (e.g., CGR use $H = 2$ in their empirical analysis). The values of H selected by the AIC are 1 quarter for BO, 1 quarter for VC, and 2 quarters for RE.

We also apply the same procedure described in the prior subsection to construct $UNNAV$ given $RPNAV$ and the unsmoothed returns. In particular, we continue to limit the unsmoothing process to the portion of each fund's life in which NAV is a reasonably large

[IA.6] Specifically, Equation IA.16 is an AR(H) process with exogenous variables f_{t-h}^o. So, we find the $\rho^{(h)}$ value that maximizes the maximum log-likelihood of the AR(H) process with exogenous f_{t-h}^o (through a generic non-linear optimization). Conditional on this $\rho^{(h)}$ value (which fixes f_{t-h}^o), we obtain the other parameters using standard MLE.

fraction of the total fund size.

Figures IA.3(d) to IA.5(d) provide the return autocorrelations for BO, VC, and RE (respectively) using aggregate returns constructed from 3-step AR unsmoothed NAVs. As it is clear from the figures, unsmoothed returns have similar autocorrelation structure (with autocorrelations relatively close to zero) whether we rely on the MA or AR unsmoothing process. In addition, as shown in Subsection 4.1, the alpha results using 3-step AR unsmoothed NAVs are very similar to the alpha results using 3-step MA unsmoothed NAVs or nowcasted NAVs.

(a) NAV / Size

Number of Years Since Inception Year

(b) Allocation Multiplier

AUM Steady State Growth Rate (g)

Figure IA.1
Private Capital Allocation Multiplier

This figure details our process for calibrating the allocation multiplier of each private capital asset class: buyout (BO), venture capital (VC), and real estate (RE). Panel (a) plots the total NAV of funds in each asset class relative to their size (i.e., total commitment) averaged over time, with the x-axis reflecting the time since the fund's inception year (i.e., the figure displays $\text{NAVf}^{(h)}$ from Equation IA.10 for a strategy in which I_v includes all funds with vintage year v). Panel (b) displays, for each asset class, λ as a function of g based on Equation IA.10 by combining the $\text{NAVf}^{(h)}$ estimates in panel (a) with different g values. Subsection 2.2 provides data details and Subsection 2.3.4 provides a description of the results in this figure.

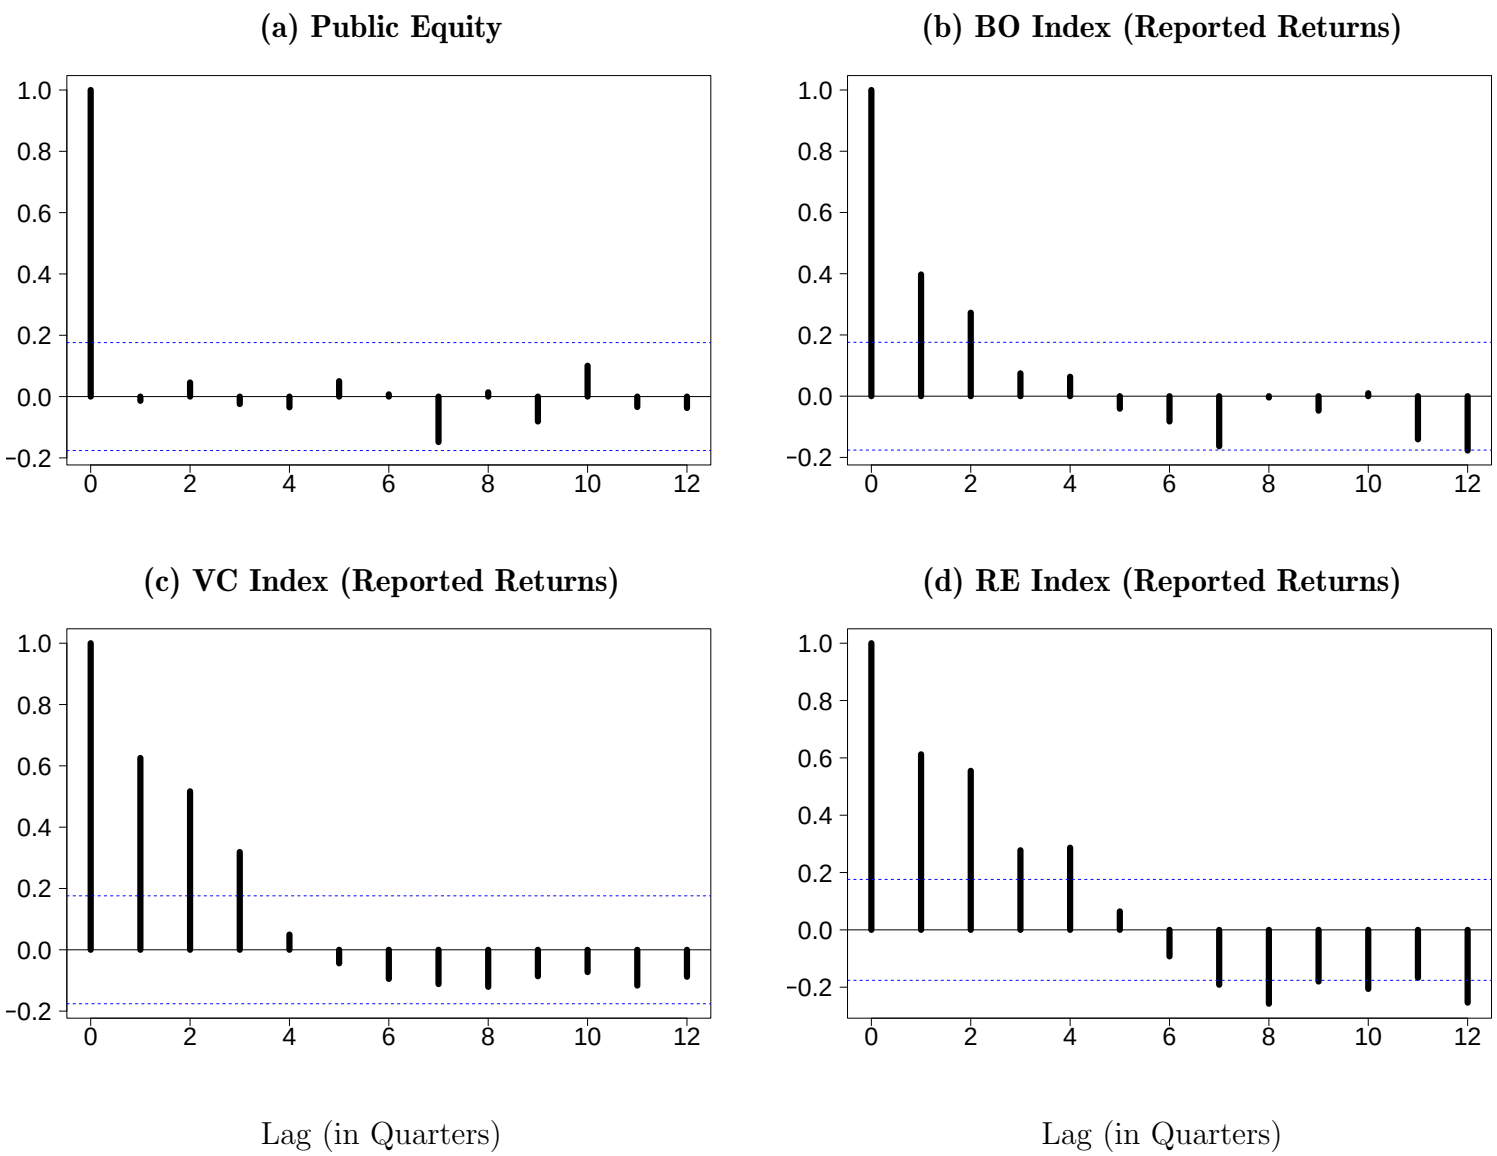

Figure IA.2
Return Autocorrelations of Aggregate Equity and Private Capital Indices

This figure plots the return autocorrelations for value-weighted private market indices. The private market indices cover buyout (BO), venture capital (VC), and real estate (RE). The returns on the private market indices are obtained using reported NAVs (Panels (a), (c), and (e)) and nowcasted NAVs from Brown, Gredil, and Kaplan (2019) to adjust for NAV smoothing (Panels (b), (d), and (f)). Subsection 2.2 provides data details and Subsection 3.2 provides a description of the results in this figure.

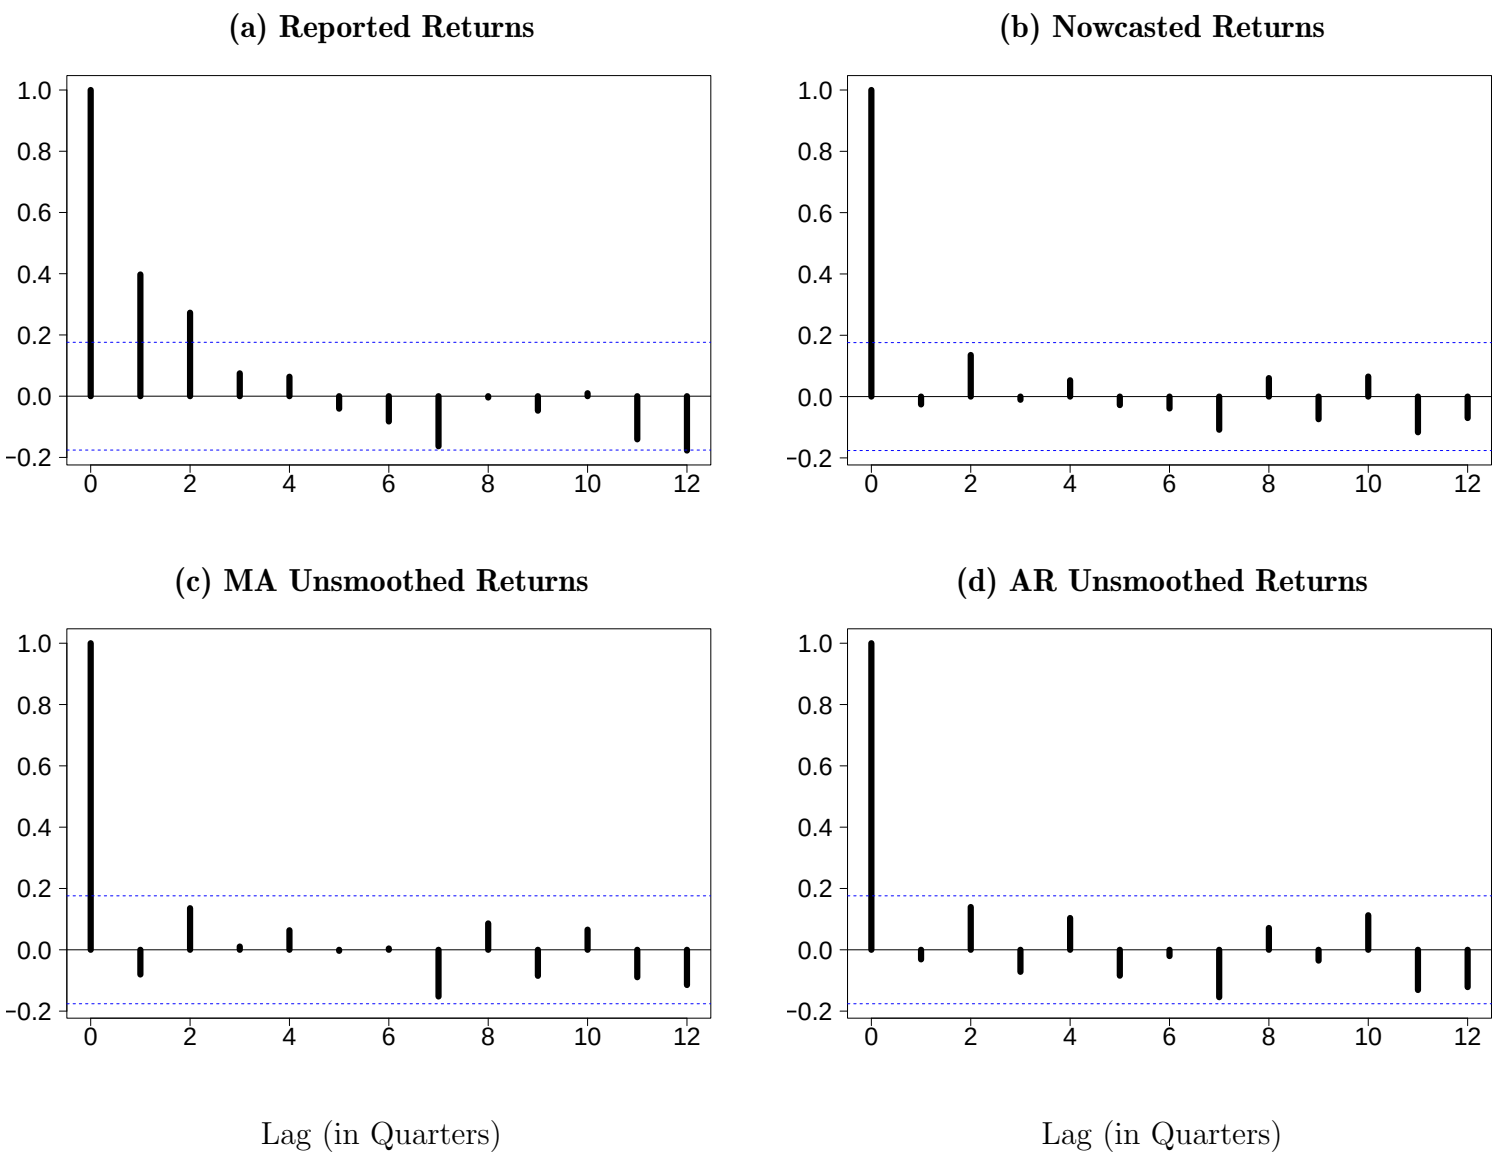

Figure IA.3
Return Autocorrelations of Aggregate Buyout (BO) Index

This figure plots the return autocorrelations for value-weighted private market indices. The private market indices cover buyout (BO), venture capital (VC), and real estate (RE). The returns on the private market indices are obtained using reported NAVs (Panels (a), (c), and (e)) and nowcasted NAVs from Brown, Gredil, and Kaplan (2019) to adjust for NAV smoothing (Panels (b), (d), and (f)). Subsection 2.2 provides data details and Subsection 3.2 provides a description of the results in this figure.

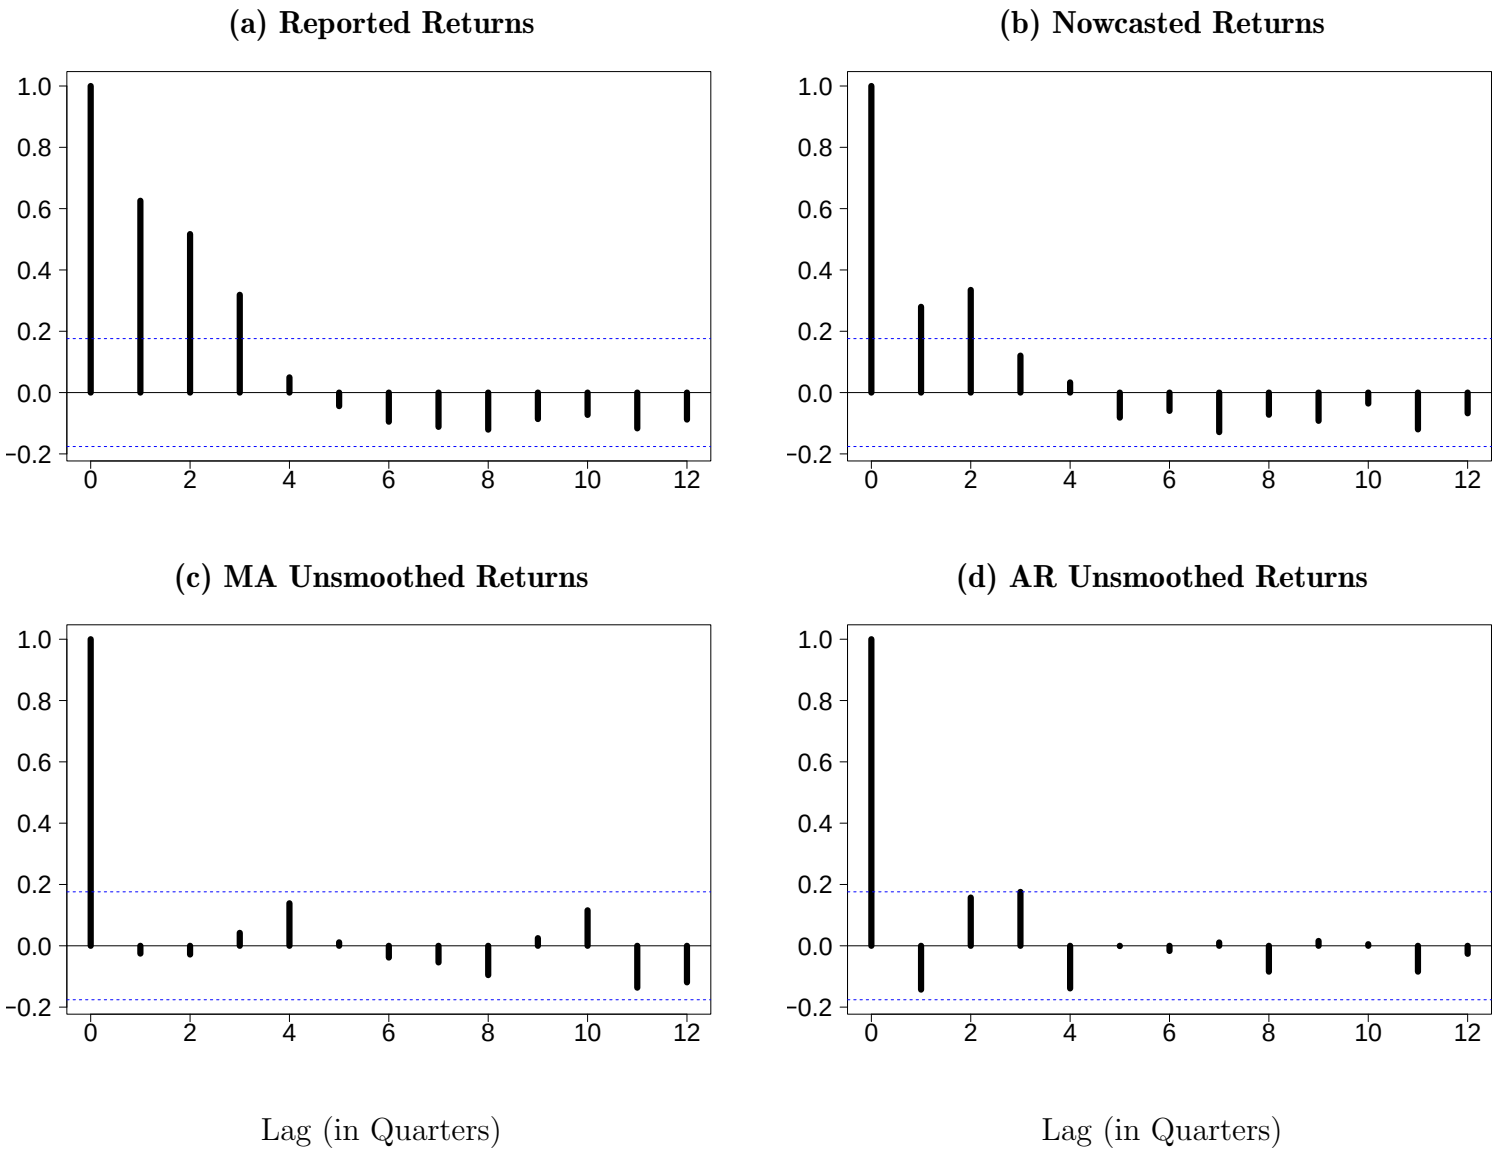

Figure IA.4
Return Autocorrelations of Aggregate Venture Capital (VC) Index

This figure plots the return autocorrelations for value-weighted private market indices. The private market indices cover buyout (BO), venture capital (VC), and real estate (RE). The returns on the private market indices are obtained using reported NAVs (Panels (a), (c), and (e)) and nowcasted NAVs from Brown, Gredil, and Kaplan (2019) to adjust for NAV smoothing (Panels (b), (d), and (f)). Subsection 2.2 provides data details and Subsection 3.2 provides a description of the results in this figure.

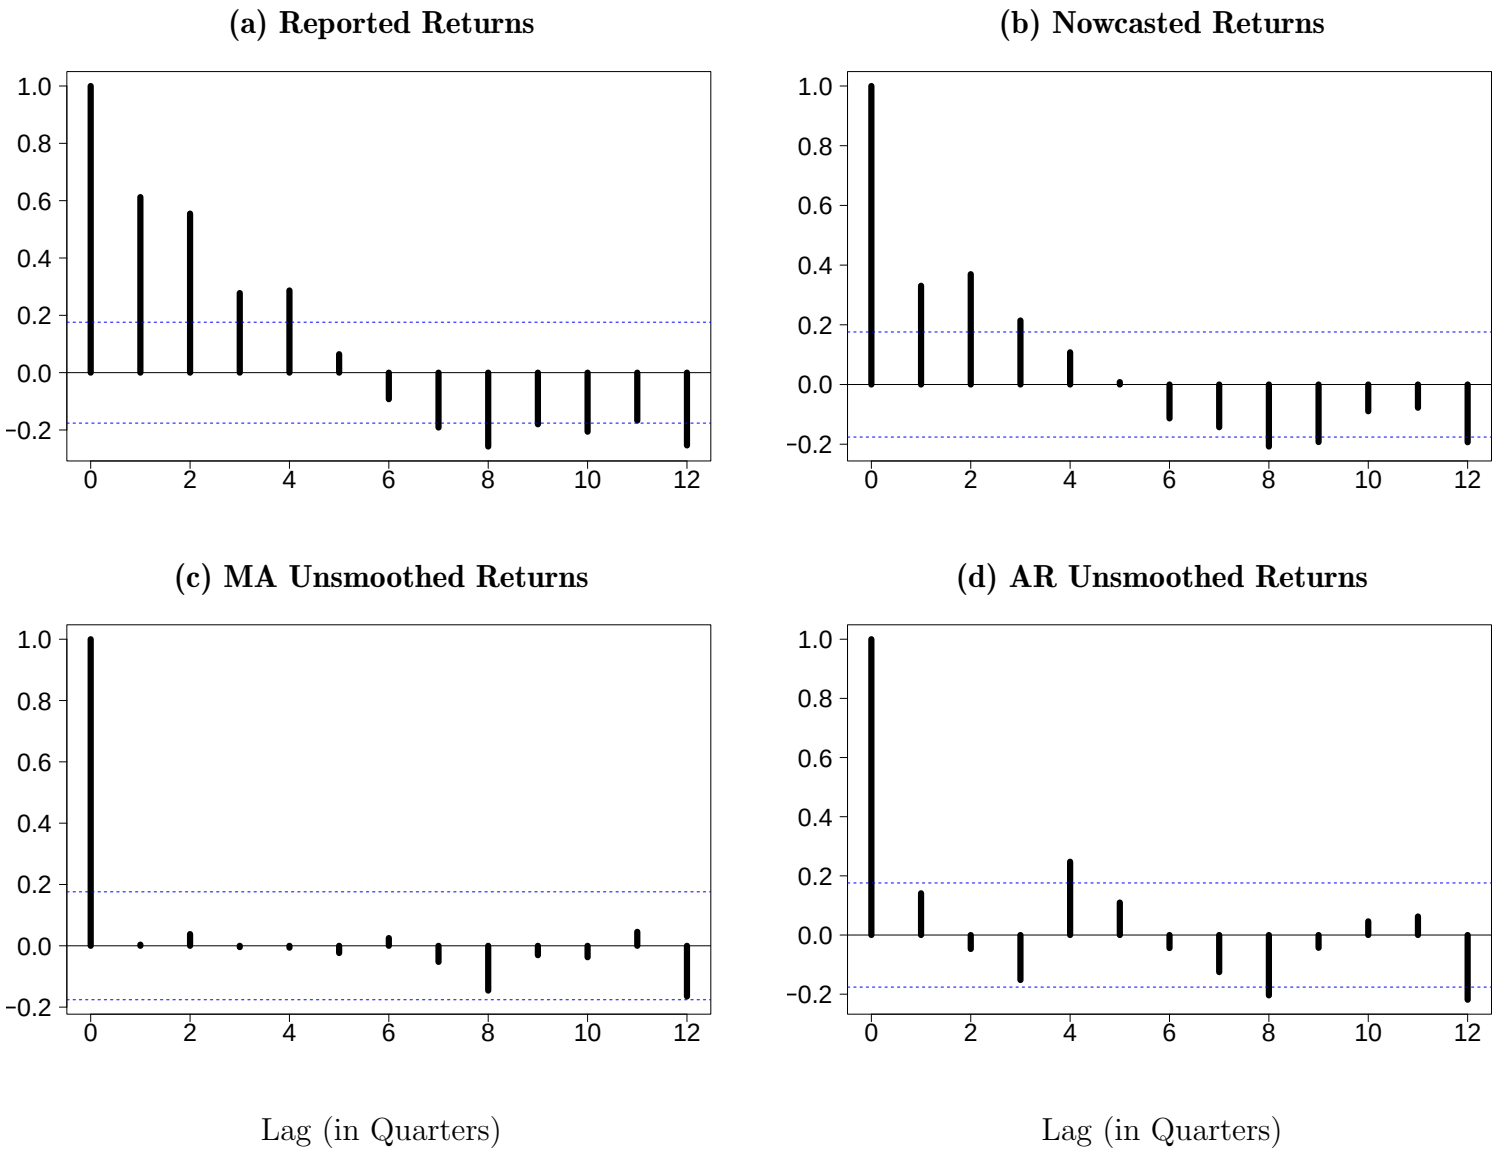

Figure IA.5
Return Autocorrelations of Aggregate Real Estate (RE) Index

This figure plots the return autocorrelations for value-weighted private market indices. The private market indices cover buyout (BO), venture capital (VC), and real estate (RE). The returns on the private market indices are obtained using reported NAVs (Panels (a), (c), and (e)) and nowcasted NAVs from Brown, Gredil, and Kaplan (2019) to adjust for NAV smoothing (Panels (b), (d), and (f)). Subsection 2.2 provides data details and Subsection 3.2 provides a description of the results in this figure.
