ABSTRACT

We open the black box of firm innovation production by examining its most important input: the teams of employees tasked with creating new inventions. Using a novel within-firm research design that tracks the universe of U.S. corporate inventors and their teams across four decades, we find that inventors' shared cultural values are a critical driver of inventor team formation. Moreover, using premature co-inventor deaths as exogenous shocks to team composition, we document both positive and negative impacts of inventor team cultural diversity on team patent production. Less culturally diverse teams produce a higher overall quantity of patents that tend to exploit existing technologies, while more culturally diverse teams produce more risky, exploratory patents with a greater potential for high-impact innovations. Exploring the underlying mechanisms, we present micro-level evidence that culturally diverse teams tend to seek new knowledge from more heterogeneous and non-traditional input information sources, but they also face greater knowledge integration challenges. Overall, our results present a more nuanced perspective on diversity, revealing that it does not lead to uniformly better or worse outcomes, but instead impacts the type of economic output.

We would like to thank Cesare Fracassi, Danielle Li, Francesco Lissoni, Xing Liu, Maria-Teresa Marchica, Yihui Pan, Rui Silva, Ting Xu, and Hanyi Yi (discussants), Lauren Cohen, Lee Fleming, Jarrad Harford, Gerard Hoberg, Josh Lerner, Kai Li, Gordon Phillips, and John Van Reenen, as well as all participants at the American Finance Association (AFA) Annual Meeting, Western Finance Association (WFA) Annual Meeting, American Economic Association (AEA) Annual Meeting, Society for Financial Studies (SFS) Cavalcade North America Annual Meeting, Financial Intermediation Research Society (FIRS) Conference, China International Conference in Finance (CICF), Society of Labor Economists (SOLE) Annual Meeting, Midwest Finance Association (MFA) Annual Meeting, Edinburgh Corporate Finance Conference, Global Entrepreneurship and Innovation Research Conference, Lone Star Finance Symposium, EPFL Innovation Seminar, University of Massachusetts, and Texas A&M University for their invaluable feedback.

1. INTRODUCTION

Technological innovation plays a pivotal role in the real economy, serving as the primary driver for sustained long-term economic growth (Schumpeter, 1942; Romer, 1990). Amid the increasing complexities of technological advancement, the rising importance of teamwork in spurring new inventions has become one of the defining features of the modern knowledge economy (Jones, 2009; Lucas and Moll, 2014; Bloom, Jones, Van Reenen, and Webb, 2020). Notably, over 80% of patents granted to U.S. public firms in recent years have been produced by teams of two or more inventors. Concurrent with this trend, the topic of diversity in the workplace has attracted significant public attention, with private companies, investors, and regulators making a conscious effort to implement policies that aim to increase workplace diversity across various dimensions.[1] This focus on diversity highlights its critical role in shaping social dynamics and economic performance, especially given the large and growing contribution of human capital to firm value and economic growth (Zingales, 2000).

In this paper, we examine what the intersection of these trends, namely increased teamwork and workplace diversity, means for inventor team formation and team-level labor productivity. We focus on the unique and economically important context of innovation production within for-profit firms, as it reflects how inventors are primarily organized in the modern innovation ecosystem.[2] However, despite firms spending over $1 trillion annually on R&D in a setting where both creativity and efficiency are deemed essential, the corporate innovation process remains a 'black box.' We open this 'black box' of firm innovation production by concentrating on its most vital input: the teams of employee inventors directly responsible for creating new inventions.

[1] For example, several government regulations require firms to take affirmative actions to ensure that equal employment opportunity is provided to all current and prospective employees (e.g., *U.S. Presidential Executive Order 11246*) or enforce explicit diversity quotas (e.g., Norway's *Public Limited Liability Companies Act (1997)*). With respect to corporate actions, 74% of S&P 500 companies have established a dedicated Chief Diversity Officer position or equivalent role, with many of these appointments occurring over the last few years (Paikeday, Qosja, Lim, and Flock, 2023).

[2] For example, over 80% of all utility patents granted by the USPTO between 1996 to 2020 are estimated to have been assigned to for-profit corporations (see USPTO Technology Assessment and Forecast (TAF) database).

Our paper specifically focuses on how diversity in the cultural values of inventor team members impacts the team's innovation process. As we explain in Section 2, this innovation process critically depends on differences in each co-inventor's thinking style and problem-solving approach. This in turn affects how the team synthesizes its members' knowledge inputs to form a new joint invention, which we term the 'knowledge integration' aspect of the R&D process. These problem-solving approaches are profoundly influenced by team members' core values, beliefs, and perspectives, which are deeply ingrained and difficult to change (March, 1991; Van den Steen, 2010). This is because core values and beliefs not only act as important filters through which individuals interpret information, but they also form the basis of mental frameworks that individuals use to draw conclusions (Schein, 1985; Donaldson and Lorsch, 1983). To capture these core values and beliefs, we use an exogenous measure based on inherited culture. This is because, unlike other inherited traits such as gender, age, and ethnicity, culture is a deeper level construct that is directly related to an individual's core values and beliefs (Stahl, Maznevski, Voigt, and Jonsen, 2010). Therefore, we focus our empirical analysis on the effect of (inherited) cultural diversity among R&D team members on team innovation output.

As a result, our paper addresses two main research questions: First, how do shared cultural values drive inventors' collaboration decisions? Second, how does inventor team cultural diversity impact team innovation output? To do so, we focus on estimating the effect of inventor team cultural diversity on the formation, knowledge integration activities, and overall productivity of corporate R&D teams in for-profit firms, which is an important empirical topic that has yet to be explored.[3]

The overall net impact of diversity in the cultural values of team members on the knowledge integration process and the resulting team R&D output is both theoretically and empirically unclear.

[3] Our paper differs from studies of culture and creativity more broadly in the management literature (e.g., Wang, Cheng, Chen, and Leung, 2019) that use small sample sizes, rely mostly on surveys and experiments involving students, and study laboratory outcomes like business plan write-ups. In contrast, we conduct a large-scale study involving all inventors across the universe of patenting U.S. public firms over 40 years. We also examine commercially viable firm inventions, a critical real economic outcome involving the allocation of talent and resources amounting to over $1 trillion annually.

From a theoretical perspective, greater disparities in the starting perspectives and thought processes of more culturally diverse team members will increase the likelihood of intra-team conflicts and miscommunications, thus impairing team productivity (e.g., Garlappi, Giammarino, and Lazrak, 2017; Kets and Sandroni, 2021). However, these more diverse perspectives can also help to foster more experimentation among R&D team members, thus increasing the potential for more creative technological solutions (e.g., Van Den Steen, 2010; Donaldson, Malenko, and Piacentino, 2020). From an empirical perspective, measurement issues arise due to data limitations in the large-scale compilation of inventor and team characteristics, leading much of the prior literature to rely on less granular, firm-level data. Furthermore, endogeneity issues arise from challenges in identifying a valid counterfactual control group, the endogenous matching of firms and employees, and unobserved factors at the industry, regional, firm, board, and CEO levels.

These issues have likely contributed to the strikingly divergent conclusions reached in the large body of empirical research on related topics. With respect to team formation, some researchers find evidence of homophily, namely the tendency of individuals to prefer to work with others who share similar personal characteristics, in other business-related contexts[4], while no such evidence exists for inventor collaborations. With respect to diversity and performance, there is much conflicting evidence in the prior literature, for example on the relationship between board diversity and firm performance[5] and, more relevantly, on the relationship between firm-wide employee diversity and firm-level innovation (e.g., Ostergaard, Timmermans, and Kristinsson, 2011; Doran, Gelber, and Isen, 2022).[6]

[4] For example, see Ishii and Xuan (2014), Gompers, Mukharlyamov, and Xuan (2016), and Calder-Wang, Gompers, and Huang (2023) in the context of directors/executives, venture capitalists, and firm founding teams, respectively.
[5] For example, see Bernile, Bhagwat, and Yonker (2018) and Griffin, Li, and Xu (2021) for studies finding a positive impact and see Adams and Ferreira (2009) and Ahern and Dittmar (2012) for studies finding a negative impact.
[6] Ostergaard et al. (2011) argues that firm-wide diversity in employees' inherited traits, calculated across the firm's entire labor force, can promote firm innovation, while Doran et al. (2022) do not find any such positive effects. Crucially, these studies measure diversity and innovation at the firm level, making it impossible to link diversity among the individuals that are the most critical and direct inputs into the innovation process (i.e., corporate inventors) to their specific innovative outputs. For example, Ostergaard et al. (2011) uses one 2006 survey of 1,600 Danish firms that the authors acknowledge "does not identify the persons who interact with each other or who are involved in the specific innovation process".

Our study addresses an important gap in the existing literature by focusing on corporate inventor teams and their cultural diversity while using several innovative approaches to tackle the associated empirical challenges. First, we integrate over two dozen different data sources and employ 'big data' techniques to construct a new database tracking all U.S. patenting inventors and their associated teams working at the universe of U.S. public firms from 1981 to 2016. Unlike prior studies relying on less granular, firm-level data to examine aggregate effects, our dataset enables us to analyze the formation and productivity of inventor teams working *within the same firm* at the *same point in time*.[7] This contrast in the level of analysis is crucial because examining the effect of aggregate firm diversity on aggregate firm output may obscure the true underlying relationship between (cultural) diversity and innovation at the actual unit of production that is ultimately responsible for creating new inventions, namely corporate R&D teams.[8] Importantly, this level of examination allows us to open the black box of corporate innovation by providing unique insights into the entire process of team innovation production, from the initial formation of teams, to knowledge integration activities, and ultimately to the development of joint innovative outputs.

Second, we compile detailed personal and professional information on all R&D teams to create a new set of output measures and input control variables at the *team-level*, including team members' technical knowledge, skills, and experiences, as well as their gender, age, and immigrant status. We also quantify the initial knowledge each inventor brings to the collaboration and the new information acquired by teams during the knowledge integration process. Third, to create our key multi-dimensional measures of inherited cultural values, we introduce a new approach that uses full-count decennial U.S. census data from 1850 to 1940 combined with large-scale demographic datasets. To

[7] Thus, we ensure that pairs of treated and control teams have similar access to physical and financial resources (by being at the same firm) and are exposed to a similar technological and competitive landscape (by working at the same time).
[8] For example, one may observe that firm A has a more diverse inventor workforce and higher R&D output than firm B. However, it is plausible that, due to homophily biases between co-workers (which is consistent with our findings in Section 4), the relatively higher patenting at firm A may in fact be driven by relatively homogenous R&D teams.

the best of our knowledge, we are the first paper to undertake the task of identifying individuals' countries of ancestry by tracing their family trees through the census records. Fourth, we employ a multi-faceted empirical strategy to mitigate potential selection effects and omitted variables concerns, including a quasi-natural experiment involving premature co-inventor deaths.

We begin our analysis by examining inventors' collaboration choices, providing new evidence that shared cultural values play a critical role in inventor team formation. We find that two similarly experienced inventors employed at the same division of the same firm in the same office are 30% more likely to work together if they share similar cultural values, which is at least as quantitatively important as a colleague's prior technical experience in explaining inventors' collaboration decisions.

Next, we study how a team's cultural value diversity impacts the team's innovation output. For identification, we use a quasi-natural experiment involving premature co-inventor deaths that provides an exogenous shock to the cultural composition of pre-existing teams. Crucially, our most restrictive heterogeneous treatment effects test allows us to directly compare the output of two treated teams working at the same firm that both experience the *same* co-inventor death, and thus experience the same absolute loss of co-inventor human capital, but one team's cultural similarity *increases* after the focal co-inventor's death while the other team's cultural similarity *decreases* after the same death.

We find that the impact of a co-inventor's death on the surviving team depends in large part on the revised composition of the remaining team members' cultural values. First, we find that treated teams that become less culturally diverse produce a significantly higher quantity of patents than teams that become more culturally diverse. Second, we show that more culturally diverse teams exhibit a greater ability to develop higher quality, breakthrough innovations that garner citations towards the top of the future patent citation distribution. Third, we show that more culturally diverse teams tend to create more risky, explorative innovations, whereas less culturally diverse teams tend to produce more exploitative patents. In other words, our combined results imply that the outputs of less

culturally diverse teams tend to fall in the middle of the patenting outcome distribution, while the outputs of more culturally diverse teams tend to fall in the tails of the patenting outcome distribution.

Interestingly, we find that these simultaneous changes in the quantity, quality, distribution, and type of output created by more vs. less culturally diverse teams has offsetting effects on overall team output. Specifically, we find that total citation-weighted patents in the overall sample (across all time periods, industries, and targeted innovation profiles) is not significantly different between more vs. less culturally diverse teams, implying the output of more culturally diverse teams is not uniformly better or worse compared to less culturally diverse teams; rather, it is simply different in nature.

We then turn to an examination of mechanisms to understand how differences in information processing across team members can explain *why* there are divergent R&D output profiles for teams with different cultural diversity. Using a unique and comprehensive dataset of all patent and non-patent citations to identify key sources of information used by teams in their R&D production process, we provide novel evidence at the inventor team level for two distinct but related channels: differences in the range of input information sources used in the idea generation/knowledge integration process and disparities in the efficiency of synthesizing the perspectives of heterogenous team members.

In the first channel, we find that more culturally diverse teams exhibit a greater propensity to seek new information outside of their existing collective body of knowledge. Moreover, our study of the types of 'new' information employed by R&D teams reveals that more culturally diverse teams tend to use more unconventional and risky knowledge resources such as foreign patents and non-patent references (e.g., academic articles), whereas less culturally diverse teams tend to rely on more proven resources like older U.S. patents. These results support our theoretical predictions that more culturally diverse teams will go beyond their current knowledge base to seek new and unconventional knowledge sources to reconcile their more frequently differing viewpoints. This greater reliance on

more diverse, less proven resources during the knowledge integration process helps to explain why culturally diverse teams produce more exploratory patents and have greater variance in R&D output.

In the second channel, we find that more culturally diverse teams are less able to develop subsequent patentable inventions within compressed time frames. This is not simply due to teams working on different types of innovation (i.e., exploitative vs. exploratory) because we control for the type of innovation that the team has previously produced. This result is consistent with our theoretical predictions about the potential downsides of increased cultural diversity, as culturally diverse teams require more time and effort to reconcile their more frequently differing viewpoints, which can hinder the efficiency of the team's knowledge integration process and lead to a lower quantity of output.

Overall, unlike prior studies that document a uniformly positive or negative impact of diversity on performance, we present a more nuanced view of the relationship between team diversity and team performance. Even for two teams with similar sets of starting inputs, namely the knowledge, skills and experiences contributed by each inventor, less culturally diverse teams produce a higher overall quantity of patents that tend to exploit existing technologies, whereas more culturally diverse teams produce more exploratory patents with a greater potential for high-impact innovations. Our results offer a novel perspective that cultural diversity has both positive *and* negative consequences for team innovation production and that the net impact depends on the type of innovation pursued.

It is important to note that we use a multi-faceted identification strategy to mitigate potential selection effects and omitted variables concerns. To account for any selection effects associated with initial (endogenous) inventor team formation, we use premature co-inventor deaths that occur after team formation to create exogenous variation in teams' cultural diversity. With respect to omitted variable concerns, we can account for any time-varying omitted variables at the firm level, including management and board diversity, because our analysis compares teams working within the same firm at the same time. At the team level, our diff-in-diff regressions not only use matched counterfactual

teams working at the same firm for identification,[9] but they also control for a comprehensive set of team-level characteristics, including existing knowledge, skills, experiences, and diversity in gender, age and immigrant status, along with team and year fixed effects. Additional tests also show that R&D teams are similar in a wide variety of fundamental characteristics prior to death, thereby supporting the parallel trends assumption in our diff-in-diff setting. Furthermore, to address the potential concern that omitted variables related to each deceased inventor's unique human capital is driving our results, we use dead co-inventor fixed effects to control for the absolute loss of a co-inventor's human capital.

Lastly, a remaining potential concern is that the relative contribution or value add of the same deceased inventor to each of their treated teams, and its consequent impact on the surviving team's subsequent innovative output, may be systematically different across more vs. less culturally diverse teams. For example, if a deceased inventor is systematically both a cultural minority in the R&D team and a team member who contributes unique specialized technical knowledge to the team, then their loss could reduce both the team's cultural diversity and the diversity of its knowledge base. If this lost knowledge contribution is also systematically related to the team's future output, it may create a spurious correlation between team cultural diversity and team innovation (see generally Kerr, 2008).

However, there are several factors that undermine the plausibility of this alternative hypothesis. First, we explicitly control for the deceased inventor's relative value-add, captured by changes in the amount and diversity of team members' knowledge, skills, and experiences (see Section 5.2.4). For example, in relation to knowledge diversity among R&D team members, we construct two variables: one based on overlap in patent technology classes, and another based on patent text similarity. We show that the impact of exogenous changes in team cultural diversity on team innovation cannot be attributed to these other post-death changes. Second, we find that team cultural diversity has very low

[9] Treated inventor teams are matched with counterfactual control teams working within the same firm based on team size, innovation profile/patenting activity, and cultural similarity (see Section 5.2.1 for more details).

correlations with other controls and diversity measures (including knowledge diversity).[10] Crucially, we show that the observed changes around death in a wide array of team attributes are insignificantly different across treated teams that become more vs. less culturally diverse post-death, which is inconsistent with the alternative hypothesis that the same co-inventor death can lead to systematically different impacts across treated teams. This is likely due to the fact that inherited culture is exogenous and conceptually antecedent to knowledge and skills acquired later in life. Third, we find that no other diversity measure based on inherited or acquired traits shows a similar multi-faceted positive *and* negative relationship with team innovation output, highlighting the distinctiveness of team cultural diversity. Fourth, using the Oster (2019) test for potential unobservable omitted variable bias, we find that to fully explain away the effect of team cultural diversity on team R&D output, selection on unobservables would need to be at least 2.1 to 3.4 times larger than selection on observables. Finally, to address any possible remaining concerns with omitted variable bias, we formulate predictions about the innovation production process, specifically knowledge integration activities, that are grounded in theory specific to culture. Consistent with our theoretical predictions, we find empirical support for two underlying mechanisms that can explain *why* team cultural diversity can have both positive *and* negative impacts on team innovation. Therefore, while it is impossible to completely prove causality in a large-scale corporate R&D setting, developing a non-culture related explanation for our results that is grounded in theory and that can *simultaneously* explain all our combined empirical findings across an array of selection, treatment, mechanisms, and robustness tests seems challenging.

Our paper contributes to several strands of literature. First, it adds to our understanding of corporate innovation, which is the primary driver of aggregate innovation in the economy. While there is an vast literature studying the relationship between various CEO-, board-, firm-, investor-,

[10] The (unsigned) correlation between our team culture measures and all team diversity measures based on knowledge, skills and experiences are less than 0.05, while its correlation with other inherited traits is between 0.02 to 0.09.

and industry-level characteristics and *firm-level* innovation (e.g., Aghion, Bloom, Blundell, Griffith, and Howitt, 2005; Aghion, Van Reenen, and Zingales, 2013; Bena and Li, 2014; Seru, 2014; Acemoglu, Akcigit, Alp, Bloom, and Kerr, 2018; Islam and Zein, 2020; Griffin et al., 2021), we delve deeper by focusing directly on the most critical element of this R&D process, namely the employees ultimately responsible for creating new technologies. Specifically, our team-based research design provides a unique perspective into the inner workings of corporate innovation production, which allows us to uncover novel team- and inventor-level factors that drive the formation, knowledge integration activities, and productivity of corporate R&D teams.

Second, our paper contributes to the growing literature on how the cultural values of employees influence corporate decisions (e.g., Liu, 2016; Pan, Siegel, and Wang, 2017; Li, Mai, Shen, and Yan, 2021). Our paper also adds to a growing strand of literature that empirically examines the effect of culture on economic outcomes (e.g., Guiso, Sapienza and Zingales, 2004). Since culture and invention share a reliance on tacit knowledge, the open-ended nature of innovation search activities offers an ideal setting for testing the impact of culture on economic value creation. Crucially, unlike prior studies that present uniformly positive or negative effects of cultural homogeneity on economic performance (e.g., Guiso, Sapienza, and Zingales, 2009; Fisman, Paravisini, and Vig, 2017), we find that cultural similarity among individuals engaged in open-ended, creative tasks can have both positive *and* negative impacts on economic productivity.

Third, there is a growing body of literature documenting the importance of co-inventor networks for individual productivity (e.g., Azoulay, Graff Zivin, and Wang, 2010; Jaravel, Petkova, and Bell, 2018). More broadly, our paper adds to research on the relation between immigration and innovation, which documents the impact of high-skilled immigrants to innovation in the U.S. (e.g., Kerr and Lincoln, 2010; Akcigit, Grigsby, and Nicholas, 2017; Sequeira, Nunn, and Qian, 2020), the role of ethnic scientific communities in facilitating cross-border technology transfer (e.g., Kerr, 2008), and

the contributions of immigrant inventors in creating knowledge spillovers with U.S.-born ("native") inventors (e.g., Bernstein, Diamond, Jiranaphawiboon, McQuade, and Pousada, 2022; Moser, Pasar, and San, 2023). Different from these studies focusing on the *individual* performance of immigrant vs. native inventors working across different institutions (e.g., self-employed, universities, corporations), we concentrate our analysis on *teams* of inventors working *within the same for-profit company*. In addition, we focus on cultural diversity because it directly affects a key part of the innovation process (i.e., the team's knowledge integration activities) and our unique culture measures allow us to explore heterogeneity *within* immigrant and native communities. Our findings also provide a more nuanced perspective on diversity by revealing its differential impact on types of economic outputs as well as identifying the specific mechanisms by which cultural diversity impacts team innovation.[11]

2. CONCEPTUAL FRAMEWORK

To understand the factors that drive the formation and productivity of corporate inventor teams, we direct our attention to the innovation process itself and the employees tasked with creating new inventions. The first key part of the innovation process that has been the focus of prior studies is the initial set of technical knowledge, skills, and experiences that each inventor brings to the R&D team (Fleming, 2001). However, there is no guarantee that these initial knowledge inputs can be effectively integrated into useful new technologies. Therefore, the second critical, yet often overlooked, part of the innovation process is how these disparate knowledge inputs are combined to form a new joint invention (Schumpeter, 1934, 1939), which we term as the 'knowledge integration' process. Together, the set of raw knowledge inputs and the integration process governing their relationship create new insights that shape the resulting inventions.

[11] For example, our evidence on both positive *and* negative effects of team cultural diversity on team R&D output contrasts with prior studies that show uniformly positive patenting outcomes of interactions between first-generation immigrant and native inventors (e.g., Bahar, Choudhury, and Rapoport, 2020; Bernstein et al., 2022). In Section 7.2.1., we directly test this effect by controlling for team immigrant diversity and find our results for team cultural diversity are unaffected.

Crucially, even though two R&D teams may possess identical sets of initial knowledge, skills, and experiences, these teams can produce divergent innovation outputs if they adopt distinct thinking styles when integrating their respective knowledge. These problem-solving approaches are dependent on team members' core values, beliefs, and perspectives, which are deep-rooted and hard to change (March, 1991; Van den Steen, 2010). This is because individuals' core values, beliefs and perspectives strongly affect how they process information and draw inferences. This in turn leads individuals to develop different intuitions, belief systems, or mental models, and can thus cause people presented with identical data to draw divergent conclusions (Donaldson and Lorsch, 1983; Schein, 1985).

Therefore, we hypothesize that a key aspect of diversity in the context of innovation production is diversity in the core values, beliefs, and perspectives of R&D team members, which we seek to capture using an exogenous measure based on inherited culture. Culture is defined as the shared values, beliefs, and preferences that characterize a particular group of people, which remain fairly unchanged from generation to generation (Hofstede, 1980; Guiso, Sapienza, and Zingales, 2006). We focus on the inherited, slow moving component of culture that is endowed at birth and is exogenous to personal and career experiences acquired later in life. Compared to other inherited traits such as gender, age, and ethnicity, culture is a deeper level construct that is more directly related to a person's core values and beliefs (Desmet, Ortuño-Ortín, and Wacziarg, 2017), and thus more likely to have a stronger impact on the creative process (Stahl et al., 2010).[12] Thus, cultural diversity within inventor teams captures inherent differences in team members' values and beliefs where such differences can foster a variety of thinking styles and problem-solving approaches within the two-part innovation process. In other words, distinct from the initial set of knowledge, skills and experiences of each team

[12] For example, Desmet et al. (2017) state that "the share of variation in culture that is explained by ethnicity is very small", as a result "cultural diversity…is not correlated with ethnic diversity" and that ethnic diversity "cannot readily be taken as a proxy for diversity in values, attitudes, and preferences." Furthermore, Stahl et al. (2010) argues that a person's other inherited traits, such as gender, age, and ethnicity, are not as directly related to an individual's core values and beliefs. Nevertheless, we separately control for the impact of gender and age diversity on team innovation.

member that represents *what* the team knows, cultural diversity relates to differences in *how* team members process, communicate, and apply their knowledge to jointly tackle novel problems.

Importantly, however, the overall net impact of diversity in the cultural values of team members on the team's knowledge integration process and the consequent innovation output is theoretically unclear. Individuals with different cultural values will tend to approach the problem of synthesizing their respective initial knowledge inputs into new technical outputs from very distinct perspectives (Gorton and Zentefis, 2023). On the one hand, greater differences in the starting perspectives and cognitive thought processes of more culturally diverse team members will increase the likelihood of intra-team conflicts and miscommunications. This idea is shown in the theory models of Van den Steen (2010), Garlappi, Giammarino, and Lazrak (2017), and Kets and Sandroni (2021) that study the effect of 'culture clashes', heterogenous beliefs, and cultural diversity on firm decisions, respectively. These differences may impede the efficiency with which disparate knowledge inputs are combined within the team's knowledge integration process to create new joint inventions. In contrast, these models also argue that teams sharing similar beliefs are unlikely to face significant coordination and communication issues, even if they have divergent initial information sets. As a result, less culturally diverse teams may be better able to produce a higher quantity of R&D output over shorter timeframes.

On the other hand, since more culturally diverse teams will more frequently face the challenge of trying to reconcile more diverse perspectives and problem-solving approaches, this will lead them to have greater willingness to experiment with alternative methods for resolving such disagreements, resulting in less conformist outcomes (Donaldson, Malenko and Piacentino, 2020; Kets and Sandroni, 2021). For example, they may seek out a broader range of information sources outside of their existing knowledge base that, when integrated with their initial knowledge set, can produce more creative and higher quality solutions compared to less culturally diverse teams (Van den Steen, 2010). This may in turn allow more culturally diverse teams to develop more explorative and impactful inventions.

Due to these dueling theoretical perspectives, the overall net impact of team cultural diversity on team innovation output remains an important open question that we seek to answer empirically. In Section 5 we specifically test for the treatment effect of team cultural diversity on the quantity, quality, distribution, and type of team R&D output. Moreover, in Section 6, we use the above theory on culture to develop specific predictions about the role of cultural diversity in the team's innovation production process. First, we test whether more culturally diverse teams are more likely to draw on new information, especially from non-traditional and riskier knowledge sources, outside of the team's pre-existing knowledge base in order to reconcile their more divergent initial perspectives. Second, we examine whether more culturally diverse teams are slower to develop new patents due to greater knowledge integration challenges among team members with more diverse beliefs and perspectives.

Before proceeding, we reiterate that the existing theory with respect to culture, combined with the fact that inherited culture is exogenous and conceptually antecedent to the knowledge, skills, and experiences that inventors acquire later in life, leads us to hypothesize and primarily test how cultural diversity affects the team's knowledge integration activities (i.e., the second part of the innovation process). As such, while it is possible that team cultural diversity may have an effect on the initial set of knowledge, skills, and experiences that each team member brings to a new collaboration (i.e., the first part of the innovation process), this question is not the focus of our paper. Instead, we take the team's initial knowledge inputs as given, and all our estimates with respect to team cultural diversity are conditioned on the amount and diversity of the focal team's knowledge, skills, and experiences.

3. DATA AND VARIABLES

3.1 Sample overview

Our analysis uses a combination of over two dozen different databases to compile large-scale information on individual inventors' careers and inherited characteristics. We first collect information on U.S. patenting from three sources: the United States Patent & Trademark Office (USPTO),

PatentsView, and the Berkeley-Fung Patent Database. PatentsView holds detailed USPTO data from 1976 onwards and includes a patent's application and grant date, technology class, inventor names and locations, patent assignee names and locations (where the assignee is usually the firm at which the research is conducted) and the number of citations by and to a patent. Then, by using the Berkeley-Fung Database (which extends the 1976–2006 NBER Patent–Compustat assignee database through to 2016) in conjunction with PatentsView assignee IDs and our own database extensions,[13] we can identify all granted patents applied for between 1976 to 2016 and assigned to U.S. public firms.

Next, we merge in the PatentsView disambiguated inventor database that assigns each inventor one time-invariant ID to track their patent output and location from 1976 onwards. It covers over 3.8 million inventors working on over 6.2 million patents granted between 1976 and 2018. Following the prior literature, we define an inventor's employer as the firm that is the patent assignee. We follow the method in Li and Wang (2023) to identify the tenure of each inventor at each corporate employer.

Our baseline patent-inventor-firm linked sample includes 698,221 unique U.S.-based inventors employed at 5,403 unique U.S. publicly listed firms and covers the period from 1976 to 2016 to ensure we have at least five years of inventor activity before 1981 and after 2011. We focus on U.S.-based inventors working at U.S. public firms because these firms are likely to have a sufficiently large pool of inventors and distinct inventor teams working in geographically proximate locations to facilitate the large-scale within-firm analysis that is the basis of our identification strategy.

3.2 Identification of inventor teams at individual firms

Using augmented PatentsView inventor IDs (which trace all patents developed by an individual across time),[14] we identify and track all teams of two or more inventors that ever collaborated on a

[13] Through a combination of algorithms designed to identify similar corporate names as well as manual data checks on firms' time-varying lists of subsidiaries in SEC filings, we augment these existing patent assignee databases by linking patents granted in more recent decades to Compustat firms (enabling greater coverage of U.S. public firms post-2006).
[14] We initially use name- and location-based algorithms to identify potential duplicate inventor ID codes (a single inventor is erroneously assigned multiple inventor IDs) and potential 'over-aggregating' inventor ID codes (patent output of two

U.S. patent and assign each team a unique identifier. This process yields over 2.7 million distinct teams that co-invent at least one patent during our 40-year sample period. This unique team ID allows us to follow the patent output, citation patterns and technological specialization of each team formed since 1976. We then use this combination of patent, inventor, and team IDs, along with assignee names, to identify all the inventors and inventor teams employed at each U.S. public firm at a given time and place. This enables us to understand the factors that drive employee collaboration decisions and to compare the performance of teams with differing levels of cultural diversity and experience.

3.3 Variable construction

In this section, we describe the independent and dependent variables used in our analysis. Appendix A provides further details on the construction of each of these variables.

3.3.1 Innovation output

We construct four sets of patent-based measures at both the individual inventor and inventor team levels to assess the quantity, quality, distribution, and type of innovation produced.

First, we measure patent quantity using the number of *Total patents* filed (and subsequently granted) in a given year, and patent quality using *Average forward citations per patent*.[15]

Next, given that more radical innovation is more likely to fall in the tail ends of the patent citation distribution (Balsmeier, Fleming, and Manso, 2017), we follow Islam and Zein (2020) and define "high impact innovations" as patents that receive citations in the highest decile of patents in that application year and Cooperative Patent Classification (CPC) sub-class (*Top 10% cited patent*).

Next, as discussed in March (1991), innovation search strategy can be characterized as the trade-off between exploitative innovation (i.e., reliance on known technologies or existing capabilities) and

---

or more distinct inventors is erroneously assigned to only one inventor ID). We then use manual data verification using LexisNexis Public Records and professional networking websites (such as LinkedIn and Relationship Science), as well as USPTO and Google searches, to update the PatentsView inventor database where clear misclassifications are identified.

[15] In unreported robustness tests, we find very similar results if we use an alternative measure of patent quality from Kogan, Papanikolaou, Seru, and Stoffman (2017) that assesses the market value of patents using stock returns.

exploratory innovation (i.e., search for technologies that are distant from existing methods). We use two measures to capture a R&D team's relative focus on exploitative innovation. The first measure is *Average back cites per patent* because patents with more back cites should correlate with patenting in more crowded and mature technology areas, consistent with a greater focus on exploitative innovation (Balsmeier et al., 2017). The second measure is *Firm self-cite ratio* that measures the percentage of back cites to patents developed by the same firm that employs the focal team. More (self) cites to the employer's previous patents indicate constraining search within previously known areas of firm expertise (more exploitative innovation), while fewer self-cites suggest a broadening of efforts to explore areas that are new to the firm (more explorative innovation) (Balsmeier et al., 2017).

Finally, following Kogan, Papanikolaou, Seru, and Stoffman (2017), we measure a team's "net total" or "overall" innovation output using *Total citation-weighted patents*.

For all our patent-based variables, we follow the extensive prior finance literature (e.g., Farre-Mensa, Hedge, and Ljungqvist, 2020) and apply the natural logarithm-transformation of one plus these non-negative patent values. Section 5.2.4 provides more discussion on how our results are robust to using alternative transformations such as the inverse hyperbolic sine transformations.

3.3.2 Cultural values of individual inventors and inventor teams

We create measures of inventors' inherited cultural values as follows, where the full procedure is described in Appendices IA.1 and IA.2. First, we identify inventors' countries of ancestry (origin) using a novel multi-layered method based on several restricted, commercial, and public datasets:

- Restricted full-count decennial U.S. census data from 1850 to 1940, containing detailed individual and household information for more than 500 million named individuals.
- Infutor's Consumer History Plus database and LexisNexis Public Records, both commercial databases that cover 270 million and 280 million individuals in the U.S., respectively. They

contain detailed demographic information including names, year of birth, gender, the first five digits of a person's social security number, current and past residential addresses.

- The Berkeley Unified Numident Mortality Database (BUNMD), which contains more than 49 million official death records from 1988 to 2005 and provides information on individuals' social security number, names, gender, race, place of birth, date of birth, date of death, and parents' names (which frequently include mothers' maiden names).

Using these databases, we identify relatives from each inventor's family tree to determine the exact countries of ancestry for 322,687 unique inventors. For the remaining inventors, we hand collect information on countries of origin using online sources (e.g., LinkedIn, Marquis Who's Who) as well as identify countries of origin for inventors based on their immigrant generations and surnames. Specifically, we identify first-generation immigrant inventors based on the first five digits of their social security numbers and determine their countries of origin based on their surnames using several public and commercial sources that are more suitable for recent immigrants.[16] Finally, for the other inventors who are most likely U.S.-born second or higher generation immigrants, we identify their countries of ancestry using the 1850 to 1940 U.S. Census records by finding potential relatives based on shared surnames. This multi-layered search procedure represents a significant methodological advancement compared to relying solely on name-based matching techniques used in prior studies.

Second, to measure the inherited cultural characteristics of inventors from a given country of origin and to capture the multi-dimensional nature of the core values and beliefs that underlie inventors' holistic perspectives, we use the well-known cultural framework of Hofstede (1980) and

[16] While the use of surnames to identify people's cultural background has been relied upon extensively in a wide variety of business disciplines including finance and accounting (e.g., Gompers et al., 2016; Liu, 2016; Pan et al., 2017; Brochet et al., 2019), we acknowledge that this method may not always yield exact matches. For instance, individuals may assume more Anglo-Saxon surnames upon entry into the U.S. In addition, married women may adopt their husbands' last names, although there is a strong tendency for females to marry men from the same cultural background as themselves (Kalmijn, 1998) and cross-cultural marriages were not common among 20th century immigrants (Pagnini and Morgan, 1990). For female inventors, we also use their maiden names provided by Infutor for matching to maximize accuracy where possible.

Hofstede, Hofstede, and Minkov (2010) that classifies national culture into six dimensions.[17] The first cultural dimension is the individualism index (IDV), which is higher when people in a society emphasize personal achievement and rights, and prioritize the needs of oneself and one's immediate families. The second dimension is the power distance index (PDI), which measures the degree to which members of the society accept the hierarchical distribution of power and unquestioningly obey authority. The third dimension is the uncertainty avoidance index (UAI), which measures the extent to which people feel threatened by ambiguity and try to avoid these situations. The fourth dimension is the masculinity index (MAS), which is higher if a society promotes masculine values like assertiveness and competitiveness and supports more traditional gender roles. The fifth dimension is the long-term orientation index (LTO), which is related to the fostering of virtues oriented towards future rewards. The sixth dimension is the indulgence index (IVR), which measures how much people try to control their desires and impulses. As described in Appendices IA.1 and IA.2, we link the Hofstede measures to inventors' countries of origin and obtain inherited cultural values for 98% of the 1.5 million U.S inventors that patent at any employer between 1981 and 2016.

We use Hofstede's framework because it is the most influential cultural framework used in many disciplines including finance.[18] The Hofstede values have been replicated by many studies using different populations (e.g., Shane, 1995; Merritt, 2000) and its stability over time has been corroborated by Beugelsdijk, Maseland, and Hoorn (2015). While Hofstede's framework has become widely accepted since 1980, it has faced some criticisms such as the over-reliance on theoretical (over

[17] By measuring specific cultural dimensions, we can capture the multi-dimensional aspects of individuals' core values and beliefs, which are deeper-level constructs that go beyond surface-level categorical (dummy) measures such as race, nationality, and ethnicity, which are less directly related to core values and beliefs (for example, individuals from different ethnicities can share similar values and beliefs while individuals within the same ethnic group can have different cultural values; also, individuals from the same nationality (esp., U.S.) can have different cultural values; see Desmet et al., 2017).
[18] Per Karolyi (2016), the Hofstede dimensions are cited/used in 2,083 publications from 1980 to 2015 across 45 journals used in the Financial Times Business School Research Rankings. In finance, this framework has been used in many studies including Chui, Titman, and Wei (2010), Ahern, Daminelli, and Fracassi (2015), and Ahmad, de Bodt and Harford (2021).

purely statistical) constructs (Karolyi, 2016). To ensure robustness, we also use other culture measures based on Schwartz (1992) and the World Value Survey and obtain similar results.[19]

Similar to our usage of Hofstede's national cultural dimensions to construct inherited cultural values for inventors, several recent studies also use Hofstede's indices to construct inherited cultural values for individuals such as CEOs (e.g., Nguyen, Hagendorff, and Eshraghi, 2018; Pan, Siegel, and Wang, 2020) and security analysts (e.g., Brochet, Miller, Naranjo, and Yu, 2019). This methodology follows the epidemiological approach from the economics literature (Fernández, 2011), and is based on the key idea that when individuals emigrate to a new country, they bring their cultural beliefs with them, leaving behind their external environment. Moreover, these immigrants pass down these beliefs to their descendants. Therefore, inherited cultural values are relevant for both immigrants and their descendants in the U.S., which refer to the U.S.-based inventors in our case. In contrast, non-cultural factors such as institutions and economic environments are indigenous to their native countries and geographically immobile, thus should not be relevant for immigrants and their descendants in the U.S.

We note that this approach does not imply that inventors have values identical to the average person in their country of ancestry; rather, it assumes inventors' cultural heritage, as measured by the prevalent preferences in their country of ancestry, significantly impacts their values and preferences. Specifically, we assume that inventors from similar cultural backgrounds tend to have more similar values than those from different cultural backgrounds. In other words, we assume that inventors are not systematically drawn from specific parts of the population such that those from similar cultural backgrounds in fact have more divergent values than those from different cultural backgrounds.

[19] In unreported robustness tests, we use two other set of measures to identify inherited cultural values. The first set of measures is from the framework of Schwartz (1992) that classifies national culture into three dimensions: embeddedness vs. autonomy, hierarchy vs. egalitarianism, and mastery vs. harmony. The second set of measures includes trust, hierarchy, and individualism constructed using the World Value Survey following Ahern et al. (2015). Note that two Hofstede dimensions, power distance (i.e., hierarchy) and individualism (i.e., autonomy), overlap with these measures.

Moreover, if cultural heritage was irrelevant due to full assimilation, we would not expect to observe any evidence of homophily or other differences between inventors from diverse cultural backgrounds.

Nevertheless, in Internet Appendix IA.3, we empirically test the relation between the Hofstede cultural values in an individual's country of ancestry and the individual's personal beliefs using individual responses to the U.S. General Social Survey. These results further validate the underlying assumption of our culture measure as well as the persistence of cultural beliefs across generations.

For our subsequent empirical tests, we measure the similarity in cultural values between a pair of inventors (i, j) by first calculating the Euclidean pairwise distance between two inventors' cultural values based on Hofstede's framework according to the following formula:

$$\begin{aligned} Pairwise\ distance_{ij} = [&(IDV_{Inventor\ i} - IDV_{Inventor\ j})^2 + (PDI_{Inventor\ i} - PDI_{Inventor\ j})^2 \\ &+(UAI_{Inventor\ i} - UAI_{Inventor\ j})^2 + (MAS_{Inventor\ i} - MAS_{Inventor\ j})^2 \\ &+(LTO_{Inventor\ i} - LTO_{Inventor\ j})^2 + (IVR_{Inventor\ i} - IVR_{Inventor\ j})^2]^{\frac{1}{2}} \end{aligned}$$

To measure cultural similarity within a team of N inventors, we calculate the average of pairwise distances in all pairs of team members using the following formula:

$$Team\ cultural\ similarity = -1 \times \frac{\sum_{i,j} Pairwise\ distance_{ij}}{\frac{N(N-1)}{2}} \quad \forall i < j$$

This measure is transformed so that its values are bounded between zero and one, where higher values indicate higher cultural similarity or less cultural diversity among the R&D team members.

3.3.3 Acquired knowledge, skill, and experience of individual inventors and inventor teams

Using the patenting history of each individual inventor, we develop several controls for the professional knowledge, skills, and experiences acquired by inventors throughout their career.

Controls for the size and diversity of an inventor team's initial knowledge base

To measure the breadth of an individual inventor's accumulated knowledge base, we first compute *Individual technical knowledge base* as the number of distinct CPC technology sub-classes in which that inventor has patented to date (see generally Verhoeven, 2023). We then define our first

set of controls for the size and diversity of a team's initial knowledge base as the team-level average and team-level standard deviation of *Individual technical knowledge base*, respectively.

At the team-level, we define three additional variables to measure the range and overlap in the collective technical knowledge of a R&D team. The first measure, *Scope of team technical knowledge,* counts the number of unique CPC technology sub-classes patented in by at least one team member prior to year t. This captures the idea that the higher the number of distinct technology classes worked in by co-inventors, the greater (and broader) is that team's starting level of technical knowledge.

To robustly control for a team's knowledge/technological diversity, we construct two additional measures, *Team technical knowledge overlap* and *Team text-based knowledge proximity*, that measure the average pairwise similarity in team members' pre-existing knowledge bases. The former relies on the overlap in the CPC technology class classification of each co-inventor's prior patents (Jaffe, 1989), whereas the latter measures the textual similarity of each co-inventor's prior patents in high-dimensional word space (based on the neural network, vector space model of Whalen, Lungeanu, DeChurch and Contractor, 2000). These alternative controls that draw on distinct patent information sources helps to ensure that our results with respect to Team cultural diversity are conditional on a team's technical knowledge diversity.[20]

Controls for the amount and diversity of an inventor team's skill

We use an inventor's observed productivity to date relative to their peers to proxy for their latent skill or talent in generating new inventions in the future. We first compute each inventor's *Total patents to date* and *Average forward cites to date per patent*, where we assume that inventors who have produced a greater quantity and/or quality of patents in the past to possess relatively higher skill.

[20] We argue that we can better capture an inventor's relevant (and more recent/practical) technical experience with their patenting record as an inventor (including information on the technology classes they have patented in) compared to their educational attainment in early adulthood. This is especially so given that most U.S. inventors since 1950 possess an undergraduate college degree in a STEM-related field of study (Baumol, Schilling, and Wolff, 2009).

For our OLS, treatment, and mechanisms tests, we control for the initial amount of inventor skill that each team member brings to the new collaboration as well as the diversity in skill across team members by computing the team-level average and the team-level standard deviation of each inventor's *Total patents to date* and *Average forward cites to date per patent*, respectively.

Controls for the amount and diversity of an inventor team's experience

We use *Years of inventor experience* to account for the potential effect of cumulative experience on future patenting output and *Average backward citations per patent* to capture an inventor's relative experience to date in pursuing more exploitative vs. explorative innovations. For our empirical tests, we control for the amount of experience that each inventor contributes to the team and the diversity in experience among team members by calculating the team-level average and standard deviation of each inventor's *Years of inventor experience* and *Average backward citations per patent*, respectively.

3.3.4 Additional control variables

We also control for *Team geographic diversity* to account for the role of physical proximity in facilitating team formation as well as the number of inventors in the focal R&D team (i.e., *Team size*).

3.4 Summary statistics

Table 1 offers summary statistics of the various characteristics of our sample of 698,221 U.S.-based inventors working at U.S. publicly listed firms (Panel A) and their associated teams (Panels B and C). Consistent with Jaravel et al. (2018), we observe that while teamwork is common among inventors employed at large firms, individual inventors usually only collaborate with a small number of other inventors during their career. This implies that co-inventor networks are relatively sticky and exert an important influence on an inventor's long-term productivity. Furthermore, we find that first-time collaborators tend to have greater similarity in their cultural values (or less distance in their cultural values). We study the role of culture and other factors that influence the formation and productivity of these co-inventor relationships in Sections 4 and 5, respectively.

4. SELECTION FACTORS IN INVENTOR TEAM FORMATION

In this part, we examine the influence of cultural values in explaining the formation of new R&D collaborations between inventors employed at the same firm.

4.1 Empirical methodology – ex ante selection

Following papers such as Dyck, Morse, and Zingales (2010) and Bena and Li (2014), we estimate the following conditional logit regressions using cross-sectional data:

$$\begin{aligned} Actual\ pair_{ij,t} = {} & \alpha + \beta_1 Coinventor\ cultural\ similarity_{ij,t-1} \\ & + \beta_2 Coinventor\ geographic\ distance_{ij,t-1} \\ & + \beta_3 Coinventor\ difference\ in\ average\ forward\ cites\ to\ date\ per\ patent_{\ ij,t-1} \\ & + \beta_4 Both\ top\ 10\%\ inventors_{ij,t-1} + \beta_5 Coinventor\ technological\ proximity_{ij,t-1} \\ & + \beta_6 Coinventor\ difference\ in\ average\ backward\ cites\ to\ date\ per\ patent_{ij,t-1} \\ & + \beta_7 Coinventor\ difference\ in\ years\ of\ inventor\ experience\ to\ date_{ij,t-1} \\ & + \beta_8 Both\ have\ 5 + years\ of\ tenure\ at\ focal\ firm_{ij,t-1} + Group\ FE + \varepsilon_{ij,t} \end{aligned} \quad (1)$$

$Actual\ pair_{ij,t}$, equals one if the inventor pair i, j represents a real, first-time collaboration formed at a U.S. public firm in year *t* ('treated pair'), and zero otherwise.[21] For each realized inventor pairing, there are two counterfactual co-inventor pairs (i.e., 'control pairs') whose construction is outlined in Section 4.2. As a result, $Group\ FE$ represents the fixed effect for each new realized pairing of co-inventors and its counterfactual control pairs of potential (but ultimately unchosen) co-inventors. As such, our coefficient estimates are based on 'within group' variation in pairwise characteristics.

Our main variable of interest in this analysis is $Coinventor\ cultural\ similarity_{ij,t-1}$ which captures the degree to which shared cultural values is a meaningful driver of realized intra-firm co-inventor pairing, after controlling for the relative difference in the knowledge, skill, work experience, and proximity of the two inventors. Appendix A defines all other variables. Following Bena and Li (2014), we use robust standard errors clustered at the 'group' level.

[21] We focus on the very first collaboration between two U.S.-based inventors working at the same U.S. public firm since this choice is unaffected by confounding factors such as experience with past collaborations and team-specific relationship capital. We use the patent application date as an objective estimate of when the collaboration begun (Jaravel et al., 2018).

4.2 Counterfactual inventor pairs

To understand which factors influence the formation of new collaborations between inventors, we use our within-firm R&D setting to construct a plausible set of potential co-inventors that were available for collaboration at the time when the focal inventor decided to collaborate with a different co-inventor. This methodology of comparing realized pairings with counterfactual pairings is similar to the one employed by Gompers et al. (2016) in the context of venture capital syndicate formation.

We start the process of generating credible counterfactual inventor pairs by first identifying each pair of inventors that actually initiate a first-time collaboration at a U.S. public firm f in year t (denote as $Inventor_{T1}$ and $Inventor_{T2}$, respectively). Next, we generate pseudo inventor pairs by partnering each of $Inventor_{T1}$ and $Inventor_{T2}$ with one potential (but ultimately unchosen) collaborator that is most comparable to the actually chosen co-inventor on the following dimensions (denote these control co-inventors as $Inventor_{C2}$ and $Inventor_{C1}$, respectively). First, the counterfactual co-inventor and the actual co-inventor must be currently employed at the same firm f in year t. Second, the pseudo co-inventor must not have ever previously collaborated with either inventor in the treated pair.[22] Third, we select the inventor with the same number of (eventually granted) patent applications to date as the actually chosen co-inventor to serve as counterfactual control co-inventors $Inventor_{C2}$ and $Inventor_{C1}$ respectively).[23] This final requirement helps to ensure that the counterfactual inventor has similar innovation experience and patenting productivity to the actually chosen collaborator.

After implementing this procedure, our initial pairwise dataset contains 1.848 million first time collaborations formed between 1981 to 2016 that involve pairs of U.S.-based inventors employed at the same public firm (realized pair $Inventor_{T1}$–$Inventor_{T2}$) and 3.521 million pseudo-control pairs

[22] Our results are very similar if we instead exclude any inventors from the counterfactual control sample who ever collaborate with either inventor in the treated pair, irrespective of whether the collaboration occurs in the future or not.
[23] If more than one inventor at the firm satisfies these three criteria for selection as a counterfactual control inventor, we follow Jaravel et al. (2018) by choosing among these potential counterfactual inventors at random.

($Inventor_{T1}$–$Inventor_{C2}$ and $Inventor_{C1}$–$Inventor_{T2}$).[24] Once we merge in our shared culture measures, we obtain a final dataset of 1.821 million treated pairs and 3.444 million control pairs.

4.3 Determinants of inventor collaboration decisions

Table 2 examines the ability of various pairwise inventor characteristics to explain the observed collaboration decisions of inventors working within the same firm. We find strong evidence that homophily drives partnering decisions in internal skilled labor markets. This result applies to both shared cultural values as well as overlaps in technical skills and relative career experience.

We first document that shared cultural values plays a critical role in the decision of inventors to form new teams with each other. For example, we find that two inventors with similar cultural values are approximately 32% more likely to work together than two otherwise comparable inventors who have a one standard deviation greater distance in their cultural values (see column (1)).[25] These findings are consistent with experimental studies such as Calder-Wang et al. (2023) who find strong homophily biases in team formation among groups of Harvard Business School MBA students.[26]

To further verify the robustness of our selection test results, we incorporate stricter filters in the formation of counterfactual control pairs as follows. First, since geographic proximity is an important driver of inventor partnering decisions (Gera, 2013), as confirmed in column (1) of Table 2, we specify that the potential (but ultimately not chosen) co-inventor must also be located within 50 miles of the actual co-inventor (see column (2) of Table 2).[27] Second, given the possibility that different

[24] In less than 2% of cases, we are unable to find any valid counterfactual control pairs that meet our criteria for inclusion in the conditional logit analysis. Given that these rare cases tend to arise in small public firms with a limited pool of R&D personnel and relatively low patenting output, we drop these observations from our final selection sample.

[25] Beyond shared culture, we show that inventors with more similarity in their acquired career experiences are more likely to collaborate with each other. For example, we find that inventors prefer to work with others that have a similar amount of prior experience as an inventor. A one standard deviation reduction (about 5 years) in the difference of general inventor experience between two co-workers raises the probability of an actual collaboration between them by approximately 9%.

[26] It is important to note that our results are not simply driven by two inventors having the same country of origin. In Table IA.2, we re-run equation (1) only on the subsample of inventor pairs where the two inventors are *not* from the same country of origin. We still find that the coefficient on our shared culture measure remains strongly positive and significant.

[27] We use a 50-mile radius cut-off as an estimate of the high likelihood that two co-inventors work in the same office location (Tian, 2011). However, our results are qualitatively unchanged if we instead use a 25-mile or 100-mile threshold.

divisions within the larger corporate entity may have differential access to firm resources and inventor talent, we define an alternative counterfactual sample using only potential (but ultimately unchosen) co-inventors that work in the same division or subsidiary of the firm at the same time (see column (3) of Table 2).[28] Finally, our most restrictive counterfactual sample requires that both treated and control co-inventor pairs must involve two inventors who are actively working: (a) in the same division of the same company *and* (b) at the same geographic location/office (see column (4) of Table 2).

Table 2 shows the results from re-estimating equation (1) with each alternative control sample. We show that even two inventors working in the same company division at the same office location are approximately 30% more likely to work with each other if there is a one standard deviation increase in the similarity of their cultural values. These are economically and statistically significant effects, especially when assessed in the context of comparing pairs of similarly experienced inventors working in the same corporate division at the same geographic location at the same point in time.

Our findings highlight a key challenge for organizations when designing workplace diversity policies. Existing efforts to promote workplace diversity tend to primarily focus on recruitment (i.e., the initial hiring of a more diverse set of people into the firm) rather than the later integration of these employees into open-ended team-based activities (Van Wanrooy et al., 2011). Our evidence of strong homophily biases within firms suggests that merely boosting the hiring of workers from more diverse backgrounds may not be sufficient to realize the full benefits of workplace diversity. Instead, firms may need to also enact policies that incentivize existing employees to form a more diverse set of R&D teams (Hjort, 2014). Otherwise, the homophily biases we document may result in the oversupply of homogenous teams within a firm, even for those targeting a more diverse initial pool of skilled labor.

[28] We identify two inventors as being part of the same division if there is an exact match on the name and location of the patent assignee in their most recent patents. For example, diversified corporations such as Tesla, Inc. will usually file patents under the specific subsidiary that created the invention (e.g., Tesla Motors Inc., Tesla Electronics Inc., etc.).

5. EFFECT OF TEAM CULTURAL DIVERSITY ON INNOVATION OUTPUT

Given our strong evidence of (cultural) homophily in corporate R&D settings, we seek to answer the natural follow-on question of whether cultural diversity enhances or impedes different types of innovation (the 'ex post treatment effect'). However, the identification challenge is that the selection of co-inventors is not a random process. For instance, inventors may target new collaborations with those from relatively different personal and professional backgrounds to pursue riskier, exploration-focused innovations. Thus, differences in the output of culturally diverse vs. non-diverse teams may be due to *selection* effects that arise from endogenous co-inventor matching or *treatment* effects. To disentangle these effects, we use exogenous changes in team cultural diversity generated by premature co-inventor deaths to identify the impact of team cultural diversity on team innovation output.

5.1 Baseline association between inventor team cultural diversity and team innovation output

While our primary identification strategy centers on a sample of inventor teams experiencing co-inventor deaths, we first analyze our entire sample of inventor teams to establish a baseline relationship between the degree of diversity in team members' cultural values and the quantity, quality, distribution, and type of innovation output produced by these teams.

We start our analysis by identifying all (eventually granted) patents applied for by two or more inventors who are working at the same U.S. publicly listed firm between 1981 and 2016 and where all team members are located within the United States at the time of patenting. We then construct yearly team-based measures of innovation output, team cultural similarity, and controls as described in Section 3.3. To create a more representative panel of patent output produced by an inventor team across time, we classify a team as 'actively' collaborating together in a given year if all members of the team are 'active' employee inventors at the same focal firm in that year (see Section 3.1 for further

details).[29] The advantage of this approach is that it can better capture the entire range of research outcomes of a R&D team (particularly failed research pursuits that do not result in a new patent) rather than only focusing on (relatively successful) R&D projects that produce observable patent output.[30] Our final sample consists of approximately 3.385 million team-year observations spanning 1981 to 2016.

5.1.1 Empirical methodology

To estimate the baseline relationship between an inventor team's cultural diversity and team innovation output, we run the following ordinary least squares (OLS) regression specification:

$$Team\ innovation_{i,t} = \alpha + \beta_1 Team\ cultural\ similarity_i + \gamma X_{i,t} + Firm \times Year\ FEs + \varepsilon_{i,t,j} \quad (2)$$

$Team\ innovation_{i,t}$ is one of the patent-based outcome measures for team i working at U.S. listed employer firm j in year t as discussed in Section 3.3.1. It is set equal to zero if the team has no patent output in that year. The construction of $Team\ cultural\ similarity_i$ is based on the method outlined in Section 3.3.2. The vector $X_{i,t}$ contains various team-level controls including the size and diversity of a team's knowledge base, the amount and diversity of individual inventors' skills in a team, the amount and diversity of career experience accumulated by team members to date, team geographic diversity, and team size (see Sections 3.3.3 and 3.3.4 for further details). We include Firm × Year fixed effects such that we compare the output of more vs. less culturally diverse teams working within the same firm at the same point in time.[31] The standard errors are clustered at the inventor team level.

[29] For example, if Inventor A, B and C (together Team 1) are identified as 'active' inventors at focal firm F between 2000–2006, 2001–2006 and 2002–2007, respectively and Team 1 (successfully) applies for two patents in 2003 only, we include Team 1 in our annual team-year panel from 2002–2006 with zero patent output in 2002 and 2004–2006.

[30] For robustness, we run an alternative specification where we only include team-year observations in which the focal team did in fact formulate at least one patent. We reach the same conclusions with similar levels of statistical significance.

[31] We cannot include Team fixed effects in an OLS setting because a team's cultural composition does not vary over time.

5.1.2 Empirical results

Table 3 presents the results of our baseline OLS regressions. Unlike much of the prior literature, we provide novel evidence that diversity in an inventor team's inherited cultural characteristics has both significant positive and negative effects on team innovation production.

First, as shown in column (1) of Table 3, we find that less culturally diverse teams produce a significantly higher overall quantity of patents than more diverse teams. This result is consistent with the organizational behavioral theory that it is relatively easier to coordinate production of immediate, quantifiable output when team members share common perspectives (e.g., Van den Steen, 2010).

Second, we document that the patents produced by more culturally diverse teams tend to be of significantly higher average quality (see column (2) of Table 3) and are more radical/breakthrough in nature (see column (3) of Table 3) than patents produced by less culturally diverse teams. This implies that while more culturally diverse teams may encounter greater difficulties in synthesizing different viewpoints (leading to a lower number of patents being created), the patents that successfully combine these more disparate perspectives tend to have a greater impact on future technological development.

Third, we show in columns (4) and (5) of Table 3 that less (more) culturally diverse teams tend to produce more exploitative (explorative) patents. This result is consistent with the notion that teams with greater homogeneity in their thought processes are more likely to search in their common-known areas of expertise for more incremental technology improvements, whereas culturally diverse teams are more likely to engage in risky research pursuits outside the boundaries of existing knowledge.

A natural final question to ask is what the net impact on "total" team-level innovation of these differences in the type of innovation produced by teams with varying cultural diversity. Interestingly, we show in column (6) that total citation-weighted patents are insignificantly different between more vs. less culturally diverse teams. This result supports a more nuanced view of the relationship between

cultural team diversity and innovation. It suggests that the innovation of more culturally diverse teams is not uniformly better or worse compared to less diverse teams; rather, it is simply different in nature.

5.2 Quasi-natural experiment involving co-inventor deaths

While the previous results indicate that more (less) culturally diverse teams tend to produce more exploratory (exploitative) innovations, it is still possible that unobserved differences in team characteristics drive both the initial decision to collaborate and subsequent team innovation output.[32] An ideal experiment to establish the treatment effect of team cultural diversity on team innovation output would be to randomly assign certain inventors to form more vs. less culturally diverse teams, thus eliminating the impact of (endogenous) co-inventor selection effects. Unfortunately, it is almost impossible to find a corporate R&D setting that convincingly approximates this ideal experiment.

However, another useful experiment would be to randomly vary team cultural diversity *after* initial collaboration decisions are made. This would enable us to identify the treatment effect of cultural diversity on team innovation while holding initial team selection effects fixed. If any differences in innovation outcomes between more vs. less culturally diverse teams are driven purely by selection, exogenous variation in cultural diversity post-team formation should have no significant effect on team innovation outcomes. In this paper, we attempt to approximate this second experiment.

Therefore, to address any remaining selection concerns, we exploit a quasi-natural experiment involving premature co-inventor deaths that allows us to observe the change in a team's innovation output after the team experiences an exogenous shock to the team's cultural diversity.

5.2.1 Triple difference-in-differences approach

Relying upon the premature death methodology used in prior studies (e.g., Azoulay et al., 2010; Jaravel et al., 2018), we examine how an inventor team's innovation production would change if there

[32] For example, inventors from certain cultural backgrounds may systematically specialize in certain technology areas and/or may choose a R&D team composition that is designed to implement certain types of R&D projects.

was an exogenous shift in the diversity of team members' cultural values. Using data from the USPTO, Infutor, LexisNexis Public Records, and the Fold3 Social Security Death File, supplemented by extensive manual verification, we exploit the premature deaths of inventors working at U.S. public firms at the time of their passing as a source of exogenous variation in the diversity of a team's cultural values to examine the change in treated team productivity around co-inventor deaths.

In our first set of treatment effect tests, we identify the impact of team cultural diversity on team innovation by using a triple diff-in-diff research design. We start our analysis by identifying a control group of inventor teams working at the same firm at the same time whose co-inventors do not pass away but who have a similar level of cultural diversity as the treated team (pre-death) and who are otherwise similar to the teams that experience a premature co-inventor death. However, we do not just compare the change in the output of treated vs. control teams around co-inventor deaths to identify the effect of cultural diversity on team performance. Crucially, a unique aspect of our setting is that a co-inventor's death can exogenously increase *or* decrease the cultural similarity of a treated team's surviving inventors. We thus compare the difference in output between treated teams whose cultural similarity *increases* post their co-inventor's death and their matched control teams vs. the difference in output between treated teams whose cultural similarity *decreases* post their co-inventor's death and their matched control teams. Under the identifying assumption that, conditional on observable team and inventor characteristics, there is no other contemporaneous shock that systematically correlates with team cultural diversity and that also systematically affects the relative outcomes of the treatment group around co-inventor death date (Gruber, 1994; see also Section 5.2.2), we can use a triple diff-in-diff regression to isolate the causal effect of team cultural diversity on team innovation.

We use equation (3) to study how changes in team cultural diversity impacts team output. We estimate this regression using a panel dataset that compares the difference in output between treated teams whose cultural similarity increased (i.e., team cultural diversity decreased) after a co-inventor's

death relative to their matched control teams versus the difference in output between treated teams whose cultural similarity decreased after a co-inventor's death relative to their matched control teams:

$$\begin{aligned} Team\ Innovation_{i,t} = \alpha + \beta_1 After_{i,t} + \beta_2 After_{i,t} \times Treated\ team_i \\ + \beta_3 After_{i,t} \times Treated\ team_i \times Team\ cultural\ similarity\ change_i \\ + \gamma X_{i,t} + Team\ FEs + Year\ FEs + \varepsilon_{i,t} \end{aligned} \quad (3)$$

$Team\ innovation_{i,t}$ is one of the patent-based outcome measures in year t (see Section 3.3.1).[33] It is set equal to zero if the team has no patent output in that year. The indicator variable, $After_{i,t}$, equals one for all years after the focal co-inventor death and zero otherwise. The indicator variable, $Treated\ team_i$, equals one for all teams that experience the shock of losing a co-inventor and zero otherwise. The continuous variable, $Team\ cultural\ similarity\ change_i$, equals the difference between the treated team's cultural similarity post the focal co-inventor's death (based on the team's surviving inventors) minus the treated team's cultural similarity prior to the death (which includes the eventually deceased inventor).[34] $Team\ cultural\ similarity\ change_i$ will thus be positive (negative) when the treated team's cultural similarity increases (decreases) post their co-inventor's death. The key coefficient of interest is β_3, which compares the relative pre- and post-death impact on team innovation for cases where treated team cultural similarity increases to cases where treated team cultural similarity decreases. We include Team fixed effects to difference away any time-invariant team-level characteristics and Year fixed effects to absorb any common time trends.[35] In additional robustness tests, we show in Table IA.4 that our results outlined in Table 5 are robust to also including Firm×Year fixed effects that filter out the effects of any time-varying firm-level characteristics.

[33] Following Jaravel et al. (2018), we examine the change in team innovative output from ten years prior to the focal co-inventor's death to ten years post-death. Our results are qualitatively unchanged with similar levels of statistical significance if we narrow our focus to the 5-year period pre- and post- the focal co-inventor's death.

[34] Treated teams only experience a change in cultural similarity when the decreased inventor departs the team while control teams don't experience any change in cultural similarity since control team membership stays constant over time.

[35] Note that Team fixed effects absorbs the *Treated team* dummy variable as well as the coefficients on *Team cultural similarity change* and *After* × *Team cultural similarity change* (noting that no control team observations experience a change in team cultural similarity throughout the pre- and post-death period).

Evidently, a co-inventor's death can induce other changes in team-related traits besides team cultural similarity (for example, the amount and diversity of team experience). As such, we explicitly control for other changes in non-culture related team variables induced by the focal co-inventor death. $X_{i,t}$ includes controls for the size and diversity of a team's knowledge base, the amount and diversity of team members' skills, the amount and diversity of team members' experience, team size, and team geographic diversity (see Section 3.3). As we explain in Section 5.2.4 and Appendix IA.4, our setup also effectively controls for the deceased inventor's *relative* contribution to each of their treated teams in terms of knowledge, skill, and experience. This is achieved through our tracking of aggregate team characteristics pre- and post-inventor death, combined with the inclusion of team fixed effects.

To implement our difference-in-differences identification approach, we identify active inventor teams working at U.S. publicly listed firms that experience the 'premature' death of one of their team members (i.e., the "treated teams") and then construct their associated "control teams." We provide a summary of this method below, while the full procedure is described in Internet Appendix IA.5.

To identify treated teams, we use Infutor's Consumer History Plus File, LexisNexis Public Records, USPTO data, and the Fold3 Social Security Death Index to find deceased inventors who:

a) Died between 1981 and 2011 (to ensure we have at least 5 years of pre- and post-death data);

b) Are employed at a U.S. publicly listed firm at the time of their death; and

c) Are no older than 60 years of age at the time of their death, following Jaravel et al. (2018).

Next, to isolate 'active' inventor teams that are likely to be genuinely impacted by the death of their colleague, we identify all teams of 3+ inventors[36] that collaborated with the deceased inventor (at the same firm) on a patent that was applied for within 3 years of the focal co-inventor's death.[37] After

[36] We exclude original two-person inventor teams (i.e., deceased inventor plus one more surviving co-inventor) because it is not feasible to calculate meaningful "team-based" diversity measures in the post-treatment period for such teams.
[37] Our empirical results are very similar if we use a 5-year 'active' cut-off threshold instead of 3 years.

merging with our database of U.S.-based inventors' various characteristics, we identify 2,637 treated teams that were actively collaborating at a U.S. public firm around their co-worker's premature death.

Next, we use the following procedure to match each treated team with a corresponding control team that does not experience a co-inventor death. We specify that each control team must:

(1) Work at the same firm and have the same team size in the pre-death period as the treated team;

(2) Have no team members that are part of an existing collaboration with any treated team member;

(3) Be actively collaborating around the time of the focal co-inventor death (i.e., have successfully patented together at least once in the 3 years leading up to their colleague's death);

(4) Have developed the same number of (eventually granted) patent applications to date as the treated team at the time of the focal co-inventor's death; and

(5) Have the closest proximity to the treated team's pre-death cultural diversity value.

We use this control team's characteristics and patenting output as the counterfactual for how the focal treated team would have performed if they did not experience the loss of their collaborator. After implementing this process, we have a final sample of 2,441 treated teams and 2,441 control teams.[38]

5.2.2 Evidence supporting identification assumptions

As stated previously, our triple diff-in-diff regressions focus on comparing the changes in R&D output for treated teams whose cultural similarity increases post their co-inventor's death (relative to their control teams) with the changes in output for treated teams whose cultural similarity decreases post their co-inventor's death (relative to their control teams). Our key identifying assumption is that, conditional on controlling for changes in observable team and inventor characteristics, randomly distributed co-inventor deaths do not cause a contemporaneous shock to an unobserved variable that

[38] We are not able to find a suitable counterfactual control team for approximately 7% of our sample. This principally occurs in smaller U.S. public firms with a more limited pool of inventors that are unaffiliated with inventors comprising the treated teams. However, in unreported tests, the unmatched treated teams do not appear to be significantly different (at least on observable characteristics) from those that do find a matching control team. Note also that *all* treated teams are included in our most restrictive heterogeneous treatment effects specification outlined in Section 5.2.4.

is systematically correlated with positive and negative changes in team cultural similarity post co-inventor death *and* the subsequent patenting output of these different sets of treated teams.

To assess the reasonableness of these underlying assumptions, we first test for whether there are significant differences in observable characteristics between treated and control teams (Roberts and Whited, 2013). As shown in Panels A and B of Table 4, we find no significant differences between the two sets of inventor teams across a range of team innovation outputs (i.e., the quantity, quality, distribution, and type of patents produced) and observable team characteristics (including average experience and technical expertise of team members) leading up to the focal co-inventor's death.

Next, to more directly evaluate the reasonableness of the key identifying assumption underlying our difference-in-differences estimator, we compare the pre-treatment output and characteristics of treated inventor teams, as well as the changes in key team characteristics around co-inventor death, divided by whether the treated team's cultural similarity does or does not increase post their co-inventor's death. We do this to evaluate the possible concern that the loss of the deceased inventor will lead to changes in another team characteristic (such as the team's technical knowledge diversity) that moves in the same direction and magnitude as the team's cultural diversity.

However, as shown in Panels C and D of Table 4, we find no significant differences between each set of treated teams leading up to their co-inventor's death. Crucially, we further show in Panel E of Table 4 that the team-specific loss of technical knowledge, skill, and experience due to the focal co-inventor's death is similar across treated teams, irrespective of whether cultural value similarity increases or decreases post-death. For example, the number of unique tech class knowledge areas that is contributed solely by the deceased inventor, as well as the distinctiveness of the deceased inventor's knowledge/experience relative to other inventors within the treated team, is insignificantly different regardless of whether the cultural similarity of the team increased or decreased post their colleague's

death.[39] This suggests that the relative importance of the distinct technical contributions of the focal deceased inventor to a given team is relatively similar across both sets of treated teams.

Furthermore, in Panel F of Table 4, we report evidence that there are no significant differences in the personal traits, professional characteristics, and productivity of the deceased inventors who exogenously depart treated teams where cultural similarity increases after their death compared to deceased inventors at treated teams where cultural similarity does not increase after their death.

Finally, we assess the validity of the parallel trend assumption in our setting by investigating the pre-treatment innovation trends between the treated and control groups (see Gao and Zhang, 2017). We define nine dummies from *Year –3* to *Year +4*, and *Year 5+* to indicate the year relative to the co-inventor death. We then re-estimate equation (3) by replacing the $After$ indicator with these nine dummies. In Figure 1, we show that none of the coefficients on the triple interaction terms (i.e., β_3) involving *Year –3, Year –2*, *Year –1*, and *Year 0* indicators are statistically significant across our main outcome variables, suggesting that the parallel trend assumption is not violated in our case.[40]

Overall, these combined results are consistent with the notion that the random distribution of inventor deaths across time and individuals represents an exogenous shock to team cultural diversity that is not systematically correlated with changes in team quality and other unobserved attributes, thus allowing us to estimate the causal effect of inventor team cultural diversity on team performance.

[39] This is captured by the variables, the *Percentage of unique tech class knowledge lost due to co-inventor death*, the *Change in Team technical knowledge overlap due to co-inventor death*, and the *Change in Team text-based knowledge proximity due to co-inventor death*, respectively (see Internet Appendix IA.4 for more details).

[40] Since innovation is a relatively long-term process (Hirshleifer, Hsu, and Li, 2013) and that random co-inventor deaths are clearly not part of a planned change in a team's patenting strategy, it is unsurprising that we do not observe an immediate change in the innovation trajectory/approach of treated inventor teams post their colleague's death.

5.2.3 Empirical results of triple differences-in-differences tests

Table 5 presents the results of our triple diff-in-diff research design where our focus is on the triple interaction coefficient β_3 in equation (3).[41] First, as shown in column (1) of Table 5, we find that teams that experience an exogenous increase in the level of team cultural value similarity (i.e., become less culturally diverse) produce a 5% higher overall quantity of patents relative to teams that exogenously become more culturally diverse. Second, in column (2), average patent quality tends to decline as teams become less culturally diverse, although this change is not statistically significant at conventional levels. Third, in column (3), we find that a decrease in team cultural similarity (or higher team cultural diversity) increases the likelihood of the team producing 'high impact' innovations by approximately 15%. Fourth, in columns (4) and (5) of Table 5, we provide evidence that teams that experience an increase (decrease) in cultural diversity following a co-inventor's death are relatively more likely to produce more exploratory (exploitative) patents. Finally, in column (6), we show that the net overall (citation-weighted) innovation output of more culturally diverse teams is not significantly different from that of less culturally diverse teams.[42] As discussed earlier, our findings are unchanged when we include Firm $\times$ Year fixed effects in our regressions (see Table IA.4).

Therefore, even when comparing R&D teams with a similar amount and diversity of knowledge, skills, and experiences, our Table 5 results support a causal interpretation that cultural diversity within an inventor team significantly impacts team output. In contrast to the prior literature that presents one directional effects of diversity, our results offer a novel perspective that team cultural diversity does not have a uniformly positive or negative effect on innovation. Instead, it significantly affects the type

[41] As an aside, the somewhat mechanical reason for the strongly negative coefficient on the *After* term in this specification is because we require all treated and control teams to have patented in the pre-treatment period (to identify active teams) but there will be some teams (both treated and control) that will not generate any patents in the post-treatment period.

[42] Note that if a less culturally diverse team produces a single patent in one year that is subsequently uncited, while a more culturally diverse team does not produce any patents during that year, the comparison in the patent quantity outcome regression would be 1 vs. 0 total patents, respectively. However, the comparison in the total citation-weighted patent outcome regression would be 0 citations for both teams. Almost a quarter of all patents never garner a subsequent citation.

of team R&D output: less culturally diverse teams generate a higher overall quantity of patents that exploit existing technologies and become moderately successful, while more culturally diverse teams create a higher share of risky, exploratory patents with more potential to become radical innovations.

5.2.4 Alternative heterogeneous treatment effects specification (treated teams only)

A potential concern with our triple diff-in-diff with matched controls approach is that it may be unreasonable to compare the innovation trajectory of a treated team, which experiences the upheaval and numerical disadvantage of a co-inventor death, with the innovation trajectory of a counterfactual control team that does not experience such turmoil. To address this potential concern, in our second set of treatment effect tests, we employ an alternative approach with a heterogeneous treatment effects specification. We only focus on the treated team subsample (where all teams experience an exogenous shock to their composition due to a co-inventor's premature death) and compare the innovation outcomes of treated teams that experience an increase in cultural value similarity after a co-inventor's death with treated teams that experience a decrease in cultural similarity post a co-inventor's death.

One of the key advantages of this alternative heterogeneous treatment effects specification is that we can include "dead co-inventor fixed effects" to control for a deceased individual's unique accumulated human capital and professional/personal traits. Essentially, this test involves comparing two sets of treated teams working at the same firm at the same time where both experience the loss of the *same* co-inventor. However, one treated team experiences an increase in cultural similarity after the co-inventor's death, while the other treated team experiences a decrease in cultural similarity.

Crucially, this test not only allows us to control for the *absolute* loss of human capital arising from a team member's death (through the inclusion of dead co-inventor fixed effects), but we can also control for the *relative* contribution or value-add of the deceased inventor to each of their

respective treated teams.[43] A potential concern regarding our refined identification strategy is that there may be a systematic relationship between changes in team cultural diversity induced by the focal co-inventor's death and the relative contribution/value-add of the deceased inventor to each of their treated teams. This alternative possibility would logically predict that teams experiencing a relatively greater (lesser) loss of value-add by the deceased inventor will experience uniformly worse (better) innovation outcomes.

With respect to this possible concern, we first note that, at a more conceptual level, our unique distributional results concerning both the positive and negative effects of team cultural diversity on team innovation output do not appear to be logically consistent with the predictions of this alternative possibility. Moreover, at an empirical level, we note that our univariate comparisons in Panels D, E, and F of Table 4 imply that the relative importance of the deceased inventor's contribution of knowledge, skills, and experiences to each specific team is similar across both sets of treated teams in this analysis. For example, we show in Panel E that the *Percentage of unique tech class knowledge lost due to the focal co-inventor's death* as well as the *Change in team technical knowledge overlap* and the *Change in team text-based knowledge proximity due to co-inventor death* are insignificantly different between treated teams whose cultural similarity increases vs. decreases post-death.[44]

Furthermore, by incorporating the change in each team's amount (and diversity) of knowledge, skills, and experiences pre- and post- the focal co-inventor's death, combined with the inclusion of team fixed effects and dead co-inventor fixed effects, we explicitly control for the unique value-add provided by the deceased inventor in terms of technical expertise to each of their respective treated teams. For example, as explained in Internet Appendix IA.4, the change in *Scope of Team technical*

[43] For example, it is possible that the loss of the only engineer on a treated team has a relatively greater (negative) impact on team patenting output than the loss of that same engineer on another team comprised solely of fellow engineers.
[44] The comparability of our treated teams, in terms of team patenting output, is further confirmed by the univariate results presented in Panel C of Table 4 as well as unreported parallel trends tests.

knowledge will implicitly capture cases in which the death of the focal co-inventor is relatively more important to the team because more unique tech class knowledge is lost upon the death of the focal co-inventor. Thus, by keeping the loss of inventor-specific human capital/skill constant (since both teams experience the exact same co-inventor death) as well as explicitly controlling for the relative knowledge, skill, and experience contributed by the focal dead inventor to each of their treated teams, we can better isolate the effect of changes in team cultural diversity on team performance.

To implement this alternative treatment test, we use the following regression specification:

$$Team\ Innovation_{i,t} = \alpha + \beta_1 After_{i,t} + \beta_2 After_{i,t} \times Team\ cultural\ similarity\ change_i + \gamma X_{i,t} + Team\ FEs + Dead\ coinventor\ FEs + Year\ FEs + \varepsilon_{i,t} \quad (4)$$

$Team\ innovation_{i,t}$, is one of the patent outcome measures described in Section 3.3.1. $After_{i,t}$ equals one for all years after the focal co-inventor death, and zero otherwise. The continuous variable, $Team\ cultural\ similarity\ change_i$, equals the treated team's cultural similarity post the focal co-inventor's death minus the team's cultural similarity pre-death (we obtain similar results if we instead use the discrete binary variable $Team\ cultural\ similarity\ increases_i$).[45] We include three set of fixed effects: *Team fixed effects*, *Year fixed effects*, and *Dead co-inventor fixed effects* (which controls for each deceased inventor's unique traits and experiences). $X_{i,t}$ includes the same controls outlined in Section 5.2.1. We also conduct (unreported) tests, analogous to those undertaken in Section 5.2.2 for our triple diff-in-diff analysis, which support the parallel trends assumption in this setting.

Table 6 shows our heterogenous treatment effects results, where we re-emphasize that all our estimates are conditional on the amount and diversity of technical knowledge, skills, and experiences across the focal team members. Consistent with our prior findings, we see that teams that experience

[45] In Internet Appendix Table IA.5, we alternatively define the indicator variable *Team cultural similarity increases* that is equal to one for treated teams that experience an increase in their team's cultural value similarity after their teammate's premature death, and zero otherwise. We reach qualitatively unchanged results with very similar levels of statistical significance to those presented using the continuous variable *Team cultural similarity change*.

an exogenous decrease in team cultural diversity tend to produce a higher overall quantity of patents that tend to be more exploitative. In contrast, teams that experience an exogenous increase in cultural diversity tend to produce more risky, more explorative patents that have a greater probability of falling into the upper tails of the future patent citation distribution. Our combined results are consistent with the idea that while more culturally diverse teams may encounter greater difficulties in synthesizing different viewpoints and communication styles that in turn leads to less total patenting, successfully combining these more disparate perspectives can foster more exploratory and high impact innovation.

As outlined in Section 3.3.1, our main tests use the natural logarithm-transformation for our patent-based dependent and independent variables. For robustness, we follow the recommendations of the recent econometrics literature (for a summary, see Aihounton and Henningsen, 2021) and re-run all our analysis in Tables 5 and 6 using the inverse hyperbolic sine transformation.[46] We find very similar results to those reported (see, for example, Table IA.6 that replicates Table 6).

6. POTENTIAL MECHANISMS AFFECTING TEAM PRODUCTION

Given the heterogenous effects of inventor team cultural diversity on team innovation outcomes, we now seek to understand the potential underlying mechanisms that may explain why diversity in the cultural values of individual inventors significantly affects team innovation output. Specifically, we examine two distinct but related channels. The first channel is related to differences in the range and type of input information sources utilized during the idea generation process. The second channel is related to disparities in the efficiency of integrating the perspectives of different team members.

6.1 Propensity to incorporate new input information sources

A common rationale for advocating diversity in various workplace settings is that individuals with different backgrounds and experiences tend to approach problems from distinct yet equally

[46] Unlike log transformations, the inverse hyperbolic sine transformation is still defined at zero while continuing to retain the useful properties of log transformations such as being more robust to outliers in right-skewed distributions.

valuable perspectives, potentially leading to more rigorously tested and higher quality solutions (Kang, Kim, and Oh, 2022). This concept is particularly applicable in team-based R&D settings when dealing with complex problems, where the optimal end output or even the optimal search process for discovering a potential solution is often highly uncertain (D'Acunto, Tate, and Yang, 2021).

One potential driver of these differing perspectives among culturally diverse workers could be large differences in the awareness and/or willingness of these individuals to consider a more diverse range of information sources as inputs into the economic production process (see Bernile et al. (2018) in the context of Boards of Directors). In our case, teams with more culturally diverse inventors may be more aware of and willing to use a broader, potentially riskier range of input knowledge sources to generate innovative ideas. These effects are likely amplified by the observation that more culturally diverse teams, which more frequently face the challenge of trying to reconcile more disparate starting viewpoints and integrate more diverse problem-solving approaches, may need to consider materials outside their existing collective knowledge base to create synthesized technical solutions. In contrast, less culturally diverse teams, who share greater similarities in their starting perspectives and thought processes, may have less incentive to consider more distant information sources and are thus more likely to leverage off their existing bank of codified knowledge (Van den Steen, 2010). Therefore, even conditional on the scope of the focal team's existing knowledge/skill set, we hypothesize that:

Prediction 1: More culturally diverse teams will exhibit a higher propensity to draw on information outside of that team's pre-existing knowledge base when developing new patents together.

Prediction 2: More culturally diverse teams will rely on more non-traditional (and thus riskier) knowledge sources as inputs into the team innovation production process.

To test our first prediction, we construct a novel "*New cite ratio*" measure that captures *how much* the focal inventor team is drawing on novel information sources relative to their pre-existing knowledge base when developing their subsequent innovations. As further explained in Internet

Appendix IA.6, this measure is computed as the total number of cites to "new knowledge" (i.e., backward citations to U.S. patents, foreign patents, or "other references" that have *not* been previously developed or cited by any member of the inventor team in any of their prior patents), divided by the total number of backward citations to any information source.

To test our second prediction, we identify the *type and risk profile* of input information sources relied upon by R&D teams. As we explain in Internet Appendix IA.6, a team's greater reliance on foreign patents and other non-patent references as their underlying source of "new-to-the-team" knowledge is a significantly riskier, though possibly more novel, problem-solving strategy than using 'mature' U.S. patents granted over 10 years ago.[47] We further hypothesize that more culturally diverse teams, which exhibit greater variation in the values and thought processes of individual team members that need to be reconciled, are more likely to be aware of and more willing to rely on non-traditional materials, namely foreign patents and other references, to help resolve their more frequent conflicts in individual perspectives. In contrast, less culturally diverse teams, with greater similarity in their problem-solving approaches, may have less incentive to search outside of the widely available bank of information contained in more tried and tested 'mature' U.S. patents (see Appendix IA.6).

We then run the following OLS regression specification where we use the same initial sample of inventor teams that patent at U.S. publicly listed firms between 1981 and 2016 (see Section 5.1.1):

$$\begin{aligned} Team\ information\ source\ ratio_i = \alpha + \beta_1 Team\ cultural\ similarity_i \\ +\beta_2 Scope\ of\ team's\ existing\ knowledge\ base\ across\ all\ information\ sources_i \\ +\gamma X_{i,t} + Firm \times Year\ FEs + \varepsilon_{i,t,j} \end{aligned} \tag{5}$$

where subscript i denotes the focal inventor team, t denotes the first year that the focal team patents together and j denotes the U.S. public firm employer $Team\ information\ source\ ratio_i$ is either *Team average new cite ratio* or the *Percentage of total backward cites to* (i) *'new' foreign patents*,

[47] This is because, for example, foreign patents and other references (like academic journals) are much less commercially proven and tested knowledge sources compared to well-known U.S. patents (Arora, Belenzon, and Sheer, 2021).

(ii) *'new' other references*, or (iii) '*new' mature U.S. patents*, respectively (see Appendix A and IA.6). We use same controls and fixed effects as in Section 5.1.1, but we also include the *Scope of team's existing knowledge base across all information sources* to control for the possibility that it is more difficult for a team to make a cite to "new knowledge" if the team's existing knowledge base is larger.

In Table 7, we provide some of the first large-scale micro-level evidence on how inventor teams gather and process information during the knowledge integration phase of the innovation process. In column (1), we find that, even among teams with a similarly sized existing knowledge base and with a similar amount of knowledge, skill, and experiential diversity, more culturally diverse teams are more likely to draw on information sources outside of their existing knowledge base compared to less culturally diverse teams. In columns (2) to (4), we further show that, when teams are searching for new knowledge to help reconcile differences and synthesize their respective knowledge to create new inventions, more culturally diverse teams are 6% and 15% more likely to rely on riskier, more unconventional resources such as foreign patents and other non-patent references, respectively.[48] In contrast, less culturally diverse teams rely much more on well-known and conventional resources, such as older U.S. patents with a readily observable history of success and usefulness.

These combined results help to explain why the output of more culturally diverse teams is more likely to end up in the tails of the patenting outcome distribution. Specifically, by relying more heavily on more diverse and less proven input knowledge sources, culturally diverse teams tend to experience relatively higher variance in their innovation outcomes (i.e., more failed searches that produce zero patents vs. the creation of relatively more exploratory, path-breaking innovations).

[48] We confirm in unreported robustness tests that our results are very similar if we exclude any cases where a corporate R&D team includes an inventor with a foreign country of origin and that team then cites a foreign patent issued by the same foreign country (i.e., a team with an inventor with Japanese cultural origin cites a Japanese-issued patent). This implies that our team-based citation pattern results are quite distinct from the findings of Kerr (2008).

6.2 Heterogenous ability to integrate individual team member perspectives

Aside from gathering information and ideas from various sources for the team to use as part of the 'knowledge integration' process, another key aspect of the innovation process is for the team to synthesize each team member's proposed ideas into a cohesive technical solution. Prior studies such as Giannetti and Zhao (2019) suggest that more diverse teams in other business-related contexts tend to experience greater difficulties in reconciling team members' differing viewpoints in an expeditious manner. These challenges faced by more diverse teams can stem from more frequent disparities in starting perspectives (Horwitz & Horwitz, 2007) or difficulties in effectively communicating opinions with team members from diverse backgrounds (Van den Steen, 2010). Therefore, even among teams with similarly sized initial information sets and similar innovative search focus, we hypothesize that:

> *Prediction 3: More culturally diverse teams will take longer to evaluate and synthesize different co-inventor perspectives when attempting to produce new patentable innovations*.

To test this prediction, we study whether less culturally diverse teams will be able to produce tangible R&D output in a shorter time frame after the team's first joint patent together (measured as the number of patents that a team produces in the one to three years *after* their first patent application together).[49]

Using the same sample of R&D teams as in Section 5.1.1, we run the following OLS regression:

$$\begin{aligned} Team\ patent\ output\ within\ y\ years_i = {} & \alpha + \beta_1 Team\ cultural\ similarity_i \\ & + \beta_2 Scope\ of\ team's\ existing\ knowledge\ base\ across\ all\ information\ sources_i \\ & + \beta_3 Degree\ of\ focus\ on\ exploitative\ innovation\ by\ team's first\ joint\ patent_i \\ & + \gamma X_{i,t} + Firm \times Year\ FEs + \varepsilon_{i,t,j} \end{aligned} \tag{6}$$

where the dependent variable is the log of one plus the number of patents produced by the team within $y = \{1, 2, 3\}$ years after the team's first patent together, i denotes the identity of the inventor team, t is the first year that the team patents together and j denotes the firm at which the team is employed.

[49] We focus on the time taken to execute *subsequent* patentable projects because we do not observe the time that elapses between the date of initial team formation and the application date of the team's first joint patent together.

We use the same set of controls and fixed effects as in Section 6.1, but we also include the *Degree of focus on exploitative innovation by the team's first joint patent together*. This measure proxies for the type of R&D projects that this team is working on together, where we expect that teams focused on exploitative (explorative) innovations will often take less (more) time to co-invent subsequent patents.

In columns (5) to (7) of Table 7, we find that more culturally diverse teams produce significantly fewer patents in the one-, two-, or three-year period after the team's first patent together relative to less culturally diverse teams, respectively. In other words, even conditional on two teams working on patents with a similar level of exploratory focus and having a similarly sized existing knowledge base, more culturally diverse inventor teams seem to take significantly longer in general to develop follow-up innovations together.[50] This supports the idea that culturally diverse teams face greater challenges in synthesizing varying perspectives in a timely manner compared to culturally homogenous teams.

7. ADDITIONAL ROBUSTNESS ANALYSIS

In this section, we conduct additional empirical analyses to assess the robustness of our previously reported selection and treatment effects results from Sections 4 and 5, respectively.

7.1 Accounting for seniority and experience in collaboration decisions

A potential concern about our selection analysis is that each inventor may not have the ability to freely choose their collaborators within the firm. For example, senior managers may dictate which inventors are assigned to work on pre-identified projects. Our first observation is that extensive survey evidence (e.g., Marvel, Griffin, Hebda, and Vojak, 2007; Corsino, Giuri, and Torrisi, 2019) shows that employee inventors, particularly those working within larger corporate R&D units, highly value and often have the freedom to select research areas and team composition as well as allocate their time across R&D projects. Furthermore, especially in our sample of large public firms that operate in

[50] As expected, the strong positive coefficient on the *Degree of focus on exploitative innovation by the team's first joint patent* implies that a team that initially produces a more exploitative patent together is much more likely to quickly develop a subsequent patent together, consistent with the idea that more exploitative innovations are faster to produce.

dynamic innovative industries, it seems unlikely that firms and their employees could feasibly foresee and dictate all potential co-inventors and future projects on which teams may work (Zhang, 2022).

Nevertheless, we empirically mitigate the above concern by focusing on a subsample of more senior and/or more accomplished inventors because they have relatively greater choice in their co-inventor selection decisions. Specifically, we restrict our sample to only include the collaboration choices of the following set of inventors who are choosing between potential co-inventors: (a) prolific or 'star' inventors (i.e., 'Top 10% Inventors'); (b) those with 10+ years of total inventor experience to date and (c) those who have worked at their current employer for 10+ years. The results are presented in Table IA.3 which re-estimates equation (1) using only the collaboration choices of more experienced and/or more prolific corporate inventors. We find that even highly skilled and/or experienced inventors are 22%–27% more likely to choose to collaborate with colleagues who share similar cultural values compared with otherwise comparably skilled candidates working in the same corporate division and office location, but who have a more divergent set of cultural beliefs.

7.2 Accounting for alternative diversity-based explanations

In this sub-section, we re-run our treatment effects tests to examine whether diversity in other inherited traits of inventors can explain our unique distributional results for innovation outcomes with respect to team cultural value diversity.

7.2.1 Team diversity in immigrant status

One dimension of 'diversity' previously studied in the prior literature is the role of first-generation immigrant inventors in facilitating two-way knowledge spillovers with native inventors and the positive consequences of these knowledge spillovers for patented innovation (see e.g., Sequeira et al., 2020; Bernstein et al., 2022; Moser, Pasar, and San, 2023; Glennon, 2024). As such, we investigate whether *Team immigrant similarity* can at least partially explain our main results (refer to Appendix IA.7 for details on the construction of the *Team immigrant similarity* measure).

Interestingly, we find that, once endogenous matching and selection effects are accounted for in our unique within-firm and heterogeneous treatment effects specification with Dead co-inventor fixed effects as well as controlling for an extensive set of acquired and inherited characteristic variables, *Team immigrant similarity* does *not* appear to have a significant impact on future team innovation output as shown in Table 8. At the same time, we find that the key coefficients on *Team cultural similarity* remain largely unchanged compared to Table 6.

Our economically significant and more nuanced results uncovering both positive and negative impacts of *Team cultural similarity* on corporate innovation highlight how our study of the effect of diversity in inventors' cultural values is distinct, both theoretically and empirically, from prior studies that compare first-generation immigrant inventors to native inventors. On a conceptual level, unlike more broad categorical inventor attributes such as an inventor's first-generation immigrant vs. non-immigrant status, we measure "deeper level" constructs such as cultural values that are directly related to an individual's values and beliefs, which are more likely to have a stronger impact on the creative process. Moreover, we have testable predictions regarding the role of cultural diversity on the innovation process that are grounded in theory specific to culture. On an empirical level, compared to these prior studies that focus on *individuals* working across different institutional environments, we study initial *team* formation and compare the innovative performance of *teams* of corporate inventors working *within the same for-profit company* at the same point in time, who have similar access to physical and financial resources (by being at the same firm) and who face a similar technological/competitive landscape (by working at the same time). Importantly, consistent with the relatively low correlation between *Team cultural similarity* and *Team immigrant similarity* (approximately 0.09), we show that the impact of *Team cultural similarity* on team innovation production is unaffected by the inclusion of *Team immigrant similarity* in our empirical analysis.

7.2.2 Team diversity in other inherited characteristics (gender and age)

To further investigate the possibility that other inherited traits can account for our results, we examine whether diversity in co-inventors' gender or age can explain our unique distributional results regarding team cultural diversity. Internet Appendix IA.7 provides details on how we construct the variables *Team gender similarity* and *Team age similarity* in our sample.

Consistent with the low sample correlation between *Team cultural similarity* with *Team gender similarity* and *Team age similarity* (0.05 and 0.02, respectively), we show in Table 8 that our previous findings regarding *Team cultural diversity* are largely unaffected by the inclusion of additional team diversity measures based on other inherited inventor traits. In fact, we find that team-level diversity in these other inherited traits (i.e., *Team gender similarity* and *Team age similarity*) appear to have minimal systematic relationship with future team performance. This is consistent with the theory that, unlike diversity in "deeper level" constructs such as cultural values that are directly related to an individual's values and beliefs, diversity in other inherited traits such as gender or age is less likely to capture fundamental differences in the information processing and communication approaches of individual inventors that in turn can meaningfully affect overall team output (Stahl et al., 2010).

7.2.3 Role of team diversity in starting technical knowledge, skills, and experience

To date, we have focused on how diversity in the perspectives and thought processes of R&D team members, captured through cultural value diversity, affects the second (knowledge integration) stage of the innovation process, *conditional* on each team's initial stock of knowledge, skills, and experiences. Notably, all results shown thus far include explicit controls for the amount and diversity of knowledge, skills, and experiences across co-inventors, where the coefficients not reported for brevity. In Table 8, we explicitly report the regression coefficients that show how diversity in the initial set of knowledge, skills, and experiences that each inventor brings to the new collaboration, serving as raw inputs into the first stage of the innovation process, can affect a team's R&D output.

Using our most restrictive heterogenous treatment effects specification with Dead co-inventor fixed effects, we first show that team-level diversity in technical knowledge, skills and experiences *does not* mirror or explain the unique combination of positive and negative effects of team cultural diversity on team innovation outcomes.[51] We also note that the size of the normalized coefficients on team cultural diversity is comparable to those for team knowledge, skill, and experience diversity, indicating the significant economic impact of team cultural diversity on innovation.[52]

Therefore, even while accounting for diversity in a team's knowledge, skills, and experiences in all our empirical tests, we reaffirm that team cultural diversity plays an economically unique role in influencing how raw knowledge inputs are synthesized into commercially viable patent outputs. This is consistent with the theory that team cultural diversity captures differences in co-inventor's values and perspectives whose effects are concentrated in the second part of the innovation process centered around knowledge integration, while diversity in starting knowledge, skills, and experiences relates primarily to the first part of the innovation process. This distinction is further reinforced by the fact that the pairwise correlation between our team-based cultural value measures and all our control variables related to knowledge, skills, and experiences, is less than 0.05 in absolute terms.[53]

7.3 Additional robustness tests

In this section, we implement several additional tests to verify the robustness of our previously reported treatment effect results to potential alternative explanations.

[51] For example, the coefficient on *Diversity of Years of inventor experience* is uniformly positive across all dependent variables in Table 8, implying that greater diversity in the professional inventor experience of R&D team members is always beneficial for both the quantity and quality of team innovation output in a commercially focused R&D setting.
[52] While we report normalized coefficients in Table 8 for ease of interpretation and comparison, all our results are virtually unchanged if we instead use non-transformed variables in our regression analysis.
[53] In other words, despite prior studies such as Kerr (2008) finding that certain ethnic groups tend to specialize in distinct technology areas, we do not observe any meaningful systematic relationship between team cultural diversity and diversity in knowledge-related inputs, especially within the confines of our quasi-natural experiment involving co-inventor deaths.

7.3.1 Accounting for non-culture related changes at treated inventor teams post-death

One potential issue with using co-inventor deaths as an exogenous source of variation in team cultural diversity is our implicit assumption that these changes in team cultural diversity are not systematically correlated with other contemporaneous changes in team characteristics, such as team experience, ability, and technology focus. We first note that we already include an extensive set of time-varying controls and multiple layers of fixed effects in all our main treatment effect regressions, while Table 4 shows that our treated and control teams are quite similar on observable characteristics in the pre-death period. Nevertheless, we augment our analysis by interacting all post-death changes in control variables, calculated as the post-death period average minus pre-death period average, with the post-death and treated dummies. For brevity, we show in Table IA.7 that our results are very similar to those from our most stringent heterogeneous treatment effects specification in Table 6. In other words, including a full set of interacted controls in our regressions cannot explain the substantial incremental impact of team cultural diversity on team patenting.

7.3.2 Form control variables based on inventor characteristics measured prior to team formation

So far, we have allowed the inventor and team characteristics (e.g., knowledge, skill etc.) that form the basis of our control variables to vary through time as inventors and their teams accumulate more patenting experience. However, given that skills and experiences acquired after team formation and/or after co-inventor death may be a somewhat endogenous process, we use an alternative method to construct control variables. Specifically, we set the value of controls in the post-team formation but pre-coinventor death period equal to the value of controls in the year prior to initial team formation, and we set the value of controls in the post-death period to the surviving team's value of

controls immediately prior to the focal co-inventor's death.[54] As shown in Table IA.8, our coefficient estimates for team culture are largely unchanged and are robust to varying control variable definitions.

7.3.3 Oster (2019) tests to assess potential bias from unobservable characteristics

To estimate how large the omitted variable bias from unobservable characteristics would need to be in order to fully explain away our documented relationship between team cultural diversity and team innovation, we use the methodology outlined in Oster (2019). Following the approach and parameter values recommended by Oster (2019), we compute Oster's δ statistic as the ratio of the correlation of unobservables with team cultural diversity to the correlation of observables with team cultural diversity that would drive the coefficients on our focal team culture measures down to zero.

Based on our calculations across our various regression specifications and outcome variables, we find that δ ranges between 2.1 to 6.8, which are all higher than the robustness benchmark of one, suggesting that our key coefficient estimates are robust to any remaining omitted variable bias. In other words, given the wide range of controls that we include in our empirical tests, it seems unlikely that our main results can be explained away by unobserved omitted variables that are approximately three to five times more important than the extensive set of observables included in our regressions. This is especially so when any such unobserved factor would need to exhibit the same (significantly) positive and negative relationship that we observe between team cultural diversity and team output.

7.3.4 Representativeness of (patenting) inventor team sample

A potential concern with our preceding analysis is that we rely on a corporate R&D team successfully obtaining at least one granted patent during their time working together to identify the team's existence in our linked patent-inventor-team-firm database. Although this is the same general limitation faced by all prior innovation-focused studies that rely on patent databases to identify

[54] We obtain very similar results if we instead base the value of post-death period control variables on surviving inventors' characteristics measured in the year prior to initial team formation.

inventor collaborations (e.g., Jaravel et al., 2018; Li and Wang, 2023), and it does not appear that this issue would significantly bias the results of our quasi-natural experiment involving co-inventor deaths in any particular direction,[55] we nevertheless undertake a novel robustness analysis utilizing scientific publications data.

As discussed in Arora et al., (2021), research conducted by corporate scientists is typically disclosed in scientific publications, even if that research does not ultimately lead to the development of a new patent. This allows us to assess whether additional intra-firm R&D collaborations, which are not captured by existing patent datasets, could potentially introduce any systematic bias to our main results. Specifically, we conduct an extensive manual search in the Web of Science Scientific Publications database for any published journal articles, working papers, and conference proceedings co-authored by a focal deceased corporate inventor within three years of their death. This search enables us to identify teams consisting solely of corporate R&D researchers who have collaborated on published (potentially patentable) firm R&D projects, even though they never developed a granted patent and are thus not observable in our linked patent datasets.[56]

We make two key observations. First, only less than 4% of the deceased treated inventors in our sample are associated with a corporate R&D-focused team that is actively seeking to develop publishable (and potentially patentable) research output around the time of their death, but these teams do not appear in our existing linked databases. This suggests that our reliance on patent databases to identify relevant inventor teams is unlikely to systematically overlook or exclude a certain segment

[55] This is because our initial quasi-natural experiment sample is conditioned on having patented together at least once *before* the focal co-inventor's death exogenously changes the team's cultural composition. Thus, all treated inventor teams, irrespective of whether their team's shared culture scores exogenously increase or decrease post-death and/or whether the team produces a patent in the post-turnover period or not, remain in the entire treatment effects sample.

[56] To do this, we first collate all papers in the *Web of Science* database where one of the author's affiliations is a U.S. publicly listed firm or one of its subsidiaries. We then use a fuzzy name matching algorithm based on author surname, first initial, and middle initial to identify potential company-affiliated scientific publications co-authored by one of our deceased inventors working at the focal U.S. public firm in the 3 years surrounding their death. We then manually verify the full names and employer affiliation of all authors on the article co-authored by one of our focal deceased inventors using office/email addresses (including whether they match a corporate inventor ID in our existing dataset).

of actually formed corporate R&D teams that could bias our main conclusions. Second, in unreported Kolmogorov-Smirnov tests, we confirm that the distribution of team cultural similarity for these "scientific publication but no patent" corporate R&D teams is not significantly different from the treated inventor teams in our sample involving the same deceased co-inventor. Therefore, while we acknowledge that we may not observe all inventor teams ever formed at U.S. public firms, it appears unlikely that we are omitting a significant number of teams of a particular cultural diversity profile from our multi-faceted research design that would substantially alter our main research findings.[57]

7.3.5 Potential replacement of deceased co-inventors

Another potential concern with our research design is whether the treated teams in our sample systematically add new team members after their colleague's death, and if so, who are these newly added members. We conduct several additional (unreported) tests to address this concern. First, we observe a high level of 'stickiness' in inventor team formation, with less than 5% of the treated teams in our sample observed to add a new member in the five years following their colleague's death. Second, we verify that the (observable) characteristics of the treated teams that choose to add a new co-inventor are not significantly different from treated teams that do not add a new co-inventor. Moreover, we observe no significant relationship between changes in treated team cultural similarity and future replacement choices. Finally, our results remain qualitatively unchanged if we exclude any patents developed by these newly re-constituted inventor teams. Taken together, these findings suggest that the potential replacement decisions are unlikely to systematically bias our main results.

[57] Relatedly, while it is possible that a team of inventors could move from working together at a publicly listed U.S. firm to a private company during their respective careers, this is a relatively rare phenomenon in our sample and is highly unlikely to meaningfully affect our main conclusions. For example, we do not observe any instances of a treated surviving inventor team subsequently moving to patent together at a private company in our main treatment sample.

8. CONCLUSION

Using information on all U.S.-based corporate inventors employed at U.S. publicly listed firms over a 40-year period, we examine how shared cultural values among R&D team members impacts the corporate innovation production process and the resulting innovative output.

First, we show that, even among comparably skilled and experienced co-workers, inventors who share similar cultural values are much more likely to collaborate on new projects. Second, we find that less culturally diverse teams produce a higher overall quantity of patents that tend to exploit existing technologies while more culturally diverse teams produce more risky, exploratory patents with a greater potential for high impact innovations. Our combined results imply that the outputs of less culturally diverse teams tend to fall in the middle of the patenting outcome distribution, while the outputs of more culturally diverse teams tend to fall in the tails of the patenting outcome distribution.

We then present novel micro-level evidence on *how* cultural diversity impacts the nature of team innovation outputs, empirically tracing the differing impacts of cultural diversity on innovation to differences in the range of input information sources used during the knowledge integration process and disparities in the efficiency of synthesizing the perspectives of heterogenous team members.

Overall, our results have important implications for the implementation of policies designed to promote innovation in a corporate R&D environment. For example, the strong homophily biases in inventor collaboration that we document point to the importance of exploration-focused firms enacting policies to incentivize existing employees to work with a more inherently diverse set of R&D team members. Our study also suggests that cultural diversity does not have a uniformly positive or negative relationship with team productivity such that firms may have a different and possibly time-varying optimal mix of diverse vs. homogenous inventor teams. We hope our paper motivates the study of important follow-on questions such as how firms can better nurture more diverse R&D teams and how local labor supply diversity can affect firm and regional economic development.

Table 1: Summary statistics

This table reports summary statistics for the entire sample of individual inventors and inventor teams working at U.S. publicly listed firms from 1981 to 2016. Panel A presents descriptive statistics, computed across the entire sample period, for individual U.S.-based inventors working at U.S. publicly listed firms. Panel B outlines descriptive statistics for inventor teams consisting of U.S.-based inventors employed at U.S. publicly listed firms. *Size of inventor team per patent* equals the number of unique inventors listed on a particular patent. *Number of teams per inventor* equals the number of unique teams of which the focal inventor is a team member over the course of the entire sample period. *Distinct co-inventors per inventor* equals the number of unique co-inventors that the focal inventor works with over the course of the entire sample period. Panel C reports pairwise characteristics for all first-time collaborations between pairs of U.S.-based inventors where that first-time collaboration occurs at a U.S. publicly listed firm between 1981 and 2016. Appendix A outlines the definition of all the variables listed.

Panel A: Individual inventor characteristics

	Mean	Median	Std. dev.
Total patents	7.43	3.00	16.79
Years of inventor experience	19.59	18.00	10.90
Individual technical knowledge base	2.47	2.00	2.81
Top 10% inventor	0.19	0.00	0.39
Average backward cites per patent	18.24	9.50	41.64
Average forward cites per patent	16.90	7.50	34.61

Panel B: Inventor team characteristics

	Mean	Median	Std. dev.
Size of inventor team per patent	3.31	3.00	1.57
Number of teams per inventor	3.19	1.00	5.61
Distinct co-inventors per inventor	6.71	4.00	8.85

Panel C: Pairwise characteristics of newly formed co-inventor pairs (at time of first collaboration)

	Mean	Median	Std. dev.
Co-inventor cultural similarity	0.62	0.60	0.22
Co-inventor geographic distance (miles)	224.57	15.31	551.62
Co-inventor difference in avg. forward cites to date per patent	1.11	0.60	2.19
Both top 10% inventors	0.07	0.00	0.26
Co-inventor tech proximity	0.21	0.00	0.35
Co-inventor difference in avg. backward cites to date per patent	0.93	0.58	1.57
Co-inventor difference in years of inventor experience to date	7.01	5.00	6.96
Both have 5+ years of tenure at focal firm	0.18	0.00	0.38

Table 2: Determinants of choice of co-inventor – Main results

This table reports the results of conditional logit models that estimate the factors affecting the choice of co-inventor (see equation (1) in Section 4.1 for further details). The dependent variable is equal to one for all new co-inventor pairwise relationships formed at a U.S. publicly listed firm during the sample period and zero for counterfactual pairs that comprise the comparison/control group. Column (1) uses other inventors working at the same firm in the same year as the new, actually formed co-inventor pair to form the counterfactual control pairs. Column (2) uses other inventors working at the same firm, in the same year and at the same office to form the counterfactual control pairs. Column (3) uses other inventors working in the same division/subsidiary of a firm at the same time to form the counterfactual control pairs. Column (4) uses other inventors working in the same division/subsidiary of a firm, in the same year and at the same office to form the counterfactual control pairs (see Sections 4.2 and 4.3 for further details). Appendix A provides definitions for all independent variables. All regression specifications include group fixed effects that comprise the focal new realized pairing of co-inventors and its (up to) two counterfactual control pairs of potential (but ultimately unchosen) co-inventors. Robust standard errors (clustered at the group level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Counter-factual group	Same firm Same year	Same firm Same year Same office	Same division Same year	Same division Same year Same office
	(1)	(2)	(3)	(4)
Co-inventor cultural similarity	0.278***	0.253***	0.256***	0.270***
	(0.005)	(0.005)	(0.005)	(0.006)
Co-inventor geographic distance	-0.403***	-0.125***	-0.358***	-0.110***
	(0.001)	(0.001)	(0.001)	(0.001)
Co-inventor difference in average forward cites to date per patent	-0.003***	-0.004***	-0.003***	-0.003***
	(0.001)	(0.001)	(0.001)	(0.001)
Both top 10% inventors	4.119**	1.555***	3.166***	1.466***
	(1.788)	(0.204)	(0.975)	(0.189)
Co-inventor tech proximity	1.776***	1.455***	1.586***	1.375***
	(0.006)	(0.005)	(0.006)	(0.005)
Co-inventor difference in average backward cites to date per patent	-0.019***	-0.018***	-0.017***	-0.016***
	(0.001)	(0.001)	(0.001)	(0.001)
Co-inventor difference in years of experience to date	-0.092***	-0.092***	-0.087***	-0.088***
	(0.002)	(0.002)	(0.002)	(0.002)
Both have 5+ years of tenure at focal firm	-0.477***	-0.384***	-0.447***	-0.373***
	(0.004)	(0.004)	(0.004)	(0.004)
Group fixed effects?	Yes	Yes	Yes	Yes
No. of observations (mil)	5,265,365	4,835,252	4,812,022	4,399,770
No. of actual pairs (mil)	1,821,150	1,752,127	1,682,644	1,608,614
No. of counter-factual pairs (mil)	3,444,215	3,083,125	3,129,378	2,791,156
Pseudo R^2	0.24	0.05	0.19	0.04

Table 3: Baseline relationship between inventor team diversity and team innovation output

This table reports how diversity in an inventor team's cultural values (namely *Team cultural similarity*) affects the type of innovation output produced by the inventor team, using the ordinary least squares (OLS) regression specification outlined in equation (2) in Section 5.1.1. We measure the quantity of team innovative output each year as *Ln(1+Total patents)*. The average quality of team innovative output is measured as *Ln(1+Average forward citations per patent)*. We measure a team's propensity for producing high impact innovations as *Ln(1+Top 10% cited patents)*. A team is designated as being more (less) focused on exploitative (explorative) innovation if they have a higher average number of backward citations per patent, *Ln(1+Average backward citations per patent)*, and a higher *Average firm self-cite ratio per patent*. Total net innovation output is measured as *Ln(1+Total citation-weighted patents)*. As outlined in Section 3.3, we include several sets of control variables for the size (and diversity) of a team's knowledge base, the amount (and diversity) of team members' skills, and the amount (and diversity) of experience accumulated by team members, as well as other controls (team size and team geographic diversity). See Appendix A for definitions of all variables used in this analysis. All regression specifications include Firm × Year fixed effects. Robust standard errors (clustered at the team level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Category of innovation outcome	Quantity of innovation	Average quality of innovation	Likelihood of high impact innovation	Relative focus on exploitative innovation		Total net innovation output
Dependent variable	Ln(1+Total patents)	Ln(1+Avg forward cites per patent)	Ln(1+Top 10% cited patents)	Ln(1+Avg back cites per patent)	Avg firm self-cite ratio per patent	Ln(1+Cite weighted patents)
	(1)	(2)	(3)	(4)	(5)	(6)
Team cultural similarity	0.005**	-0.004**	-0.002**	0.004**	0.002**	-0.000
	(0.002)	(0.002)	(0.001)	(0.002)	(0.001)	(0.002)
Controls for size & diversity of team knowledge base	Yes	Yes	Yes	Yes	Yes	Yes
Controls for amount & diversity of team skill	Yes	Yes	Yes	Yes	Yes	Yes
Controls for amount & diversity of team experience	Yes	Yes	Yes	Yes	Yes	Yes
Other controls	Yes	Yes	Yes	Yes	Yes	Yes
Firm × Year fixed effects	Yes	Yes	Yes	Yes	Yes	Yes
Number of observations	3,385,004	3,385,004	3,385,004	3,385,004	3,385,004	3,385,004
Adjusted R^2	0.23	0.18	0.08	0.19	0.07	0.16

Table 4: Evidence supporting the validity of experimental design using co-inventor deaths

This table reports summary statistics that compare the inventor teams that form the basis of our difference-in-difference tests involving premature co-inventor deaths. Panels A and B focus on comparing inventor teams that experience a co-inventor death ('treated' teams) with inventor teams active in the same firm at the same point in time that do not experience the loss of a team member ('control' teams) (see Section 5.2.1 for additional details for the construction of control teams). Panel A compares the average output of treated and control firms in the 5 years up to and including the year of the focal co-inventor death while Panel B compares the average pre-treatment characteristics of treated and control teams at the time of the focal co-inventor's death. In contrast, Panels C to F focus on comparing treated inventor teams whose cultural similarity increases post their focal co-inventor's death with treated inventor teams whose cultural similarity does not increase post their focal co-inventor's death. Panel C compares the average output of these treated teams in the 5 years up to and including the year of the focal co-inventor's death while Panel D compares the average pre-treatment characteristics of these treated teams at the time of the focal co-inventor's death. Panel E compares the change in various key fundamental characteristics of these treated teams immediately around co-inventor death date that is the result of the premature loss of a co-inventor by the focal treated team. Finally, Panel F compares the observable characteristics of individual deceased inventors at the time of their death for treated teams whose cultural similarity does increase post the focal co-inventor's death compared to the characteristics of focal deceased inventors at treated teams whose cultural similarity does not increase after the focal co-inventor's death. See Appendix A for definitions of all dependent and independent variables listed. *, ** and *** indicate that the difference in means is statistically significant at the 10%, 5% and 1% level respectively.

Panel A: Average annual output in the 5-year period prior to the focal co-inventor's death

	Treated team Mean (1)	Control team Mean (2)	Difference (1) – (2)
Total patents	0.27	0.26	0.01
Average forward cites per patent	0.30	0.29	0.01
Top 10% cited patents	0.04	0.04	0.00
Average backward cites per patent	0.36	0.35	0.01
Average firm self-cite ratio per patent	0.03	0.03	-0.00
Total citation-weighted patents	0.40	0.38	0.02

Panel B: Team characteristics at the time of the focal co-inventor's death

	Treated team Mean (1)	Control team Mean (2)	Difference (1) – (2)
Team cultural similarity	0.58	0.59	-0.01
Team geographic diversity	260.55	280.72	-20.18
Scope of team technical knowledge	6.96	7.01	-0.05
Team average of individual technical knowledge base	2.82	2.84	-0.02
Team technical knowledge overlap	0.63	0.64	-0.01
Team text-based knowledge proximity	0.56	0.58	-0.02
Team average total number of patents in last 5 years	6.81	6.87	-0.06
Team average forward cites to date per patent	1.17	1.16	0.01
Team average inventor experience to date	8.48	8.35	0.13
Team average backward cites to date per patent	1.22	1.26	-0.05

Panel C: Average annual output in the 5-year period prior to the focal co-inventor's death

	Treated team (Cultural sim. Does increase) Mean (1)	Treated team (Cultural sim. Does not increase) Mean (2)	Difference (1) – (2)
Total patents	0.30	0.32	-0.02
Average forward cites per patent	0.34	0.34	0.00
Top 10% cited patents	0.06	0.06	0.00
Average backward cites per patent	0.36	0.41	-0.05
Average firm self-cite ratio per patent	0.03	0.03	-0.00
Total citation-weighted patents	0.48	0.50	-0.02

Panel D: Team characteristics at the time of the focal co-inventor's death

	Treated team (Cultural sim. Does increase) Mean (1)	Treated team (Cultural sim. Does not increase) Mean (2)	Difference (1) – (2)
Team cultural similarity	0.56	0.57	-0.01
Team geographic diversity	269.64	258.42	11.21
Scope of team technical knowledge	6.85	7.14	-0.29
Team average of individual technical knowledge base	2.87	2.80	0.07
Team technical knowledge overlap	0.64	0.64	0.01
Team text-based knowledge proximity	0.58	0.56	0.02
Team average total number of patents in last 5 years	6.61	7.08	0.47
Team average forward cites to date per patent	1.24	1.19	0.05
Team average inventor experience to date	8.90	8.57	0.33
Team average backward cites to date per patent	1.24	1.25	-0.01

Panel E: Change in key team characteristics that is directly due to the focal co-inventor's death (defined as the post-death team value minus the pre-death team value)[1]

	Treated team (Cultural sim. Does increase) Mean (1)	Treated team (Cultural sim. Does not increase) Mean (2)	Difference (1) – (2)
Percentage (%) change in scope of team technical knowledge/unique tech class knowledge	-0.07	-0.06	-0.01
% change in team average of individual technical knowledge base	-0.02	-0.02	0.00
Change in team technical knowledge overlap	0.04	0.04	0.00
Change in team text-based knowledge proximity	0.06	0.07	-0.01
% change in team average total number of patents in last 5 years	-0.03	-0.02	-0.01
% change in team average forward cites per patent	-0.03	-0.03	-0.00
% change in team average inventor experience to date	-0.03	-0.03	0.00
% change in team average backward cites per patent	-0.01	-0.02	0.01

[1] Note that negative values for a variable change implies a decline in that team characteristic post-death (e.g., a negative value for *Percentage change in unique tech class knowledge* is equivalent to the *Percentage of unique tech class knowledge "lost" due to the focal co-inventor's death*).

Panel F: Individual deceased inventor characteristics at the time of their death

	Treated team (Cultural sim. Does increase) Mean (1)	Treated team (Cultural sim. Does not increase) Mean (2)	Difference (1) – (2)
Age at time of death (years)	48.28	47.80	0.48
Individual technical knowledge base	3.00	2.94	0.06
Total patents in 5 years pre-death	7.36	7.47	-0.11
Average forward cites per patent	1.32	1.27	0.05
Top 10% cited patents	0.47	0.46	0.01
Years of inventor experience	9.13	8.98	0.15
Average backward cites per patent	1.27	1.30	-0.03

Table 5: Innovation output around exogenous co-inventor turnover – Triple difference-in-difference tests

This table reports the change in innovative output for treated teams around the death of a co-inventor relative to control teams as defined in equation (3) in Section 5.2.1. *After*$_{i,t}$ is an indicator variable equal to one for all years after the focal co-inventor's death and zero otherwise. *Treated team*$_i$ is an indicator variable equal to one for all teams that experience the death of a team member and zero otherwise. *Team cultural similarity change*$_i$ is a continuous variable equal to the surviving team's cultural similarity post the focal co-inventor's death minus the pre-death/pre-treatment team's cultural similarity. We measure the quantity of team innovative output each year as *Ln(1+Total patents)*. The average quality of team innovative output is measured as *Ln(1+Average forward citations per patent)*. We measure a team's propensity for producing high impact innovations as *Ln(1+Top 10% cited patents)*. A team is designated as being more (less) focused on exploitative (explorative) innovation if they have higher *Average backward citations per patent* and a higher *Average firm self-cite ratio per patent*. Total net innovation output is measured as *Ln(1+Total citation-weighted patents)*. As outlined in Section 3.3, we include several sets of control variables for the size (and diversity) of a team's knowledge base, the amount (and diversity) of team members' skills, and the amount (and diversity) of experience accumulated by team members, as well as other controls (team size and team geographic diversity). See Appendix A for definitions of all variables used in this analysis. All regression specifications include Team and Year fixed effects. Robust standard errors (clustered at the team level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Category of innovation outcome	Quantity of innovation	Average quality of innovation	Likelihood of high impact innovation	Relative focus on exploitative innovation		Total net innovation output

Table 6: Heterogeneous treatment effects around co-inventor deaths (treated teams only)

This table reports the change in innovative output for treated teams only around the death of a co-inventor (see equation (4) in Section 5.2.4 for further details). *After*$_{i,t}$ is an indicator variable equal to one for all years after the focal co-inventor's death and zero otherwise. *Team cultural similarity change*$_i$ is a continuous variable equal to the surviving team's cultural similarity post the focal co-inventor's death minus the pre-death/pre-treatment team's cultural similarity. We measure the quantity of team innovative output each year as *Ln(1+Total patents)*. The average quality of team innovative output is measured as *Ln(1+Average forward citations per patent)*. We measure a team's propensity for producing high impact innovations as *Ln(1+Top 10% cited patents)*. A team is designated as being more (less) focused on exploitative (explorative) innovation if they have higher *Average backward citations per patent* and a higher *Average firm self-cite ratio per patent*. Total net innovation output is measured as *Ln(1+Total citation-weighted patents)*. As outlined in Section 3.3, we include several sets of control variables for the size (and diversity) of a team's knowledge base, the amount (and diversity) of team members' skills, and the amount (and diversity) of experience accumulated by team members, as well as other controls (team size and team geographic diversity). See Appendix A for definitions of all variables used in this analysis. All regression specifications include Individual dead co-inventor fixed effects, Team fixed effects and Year fixed effects. Robust standard errors (clustered at the team level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Table 7: Mechanism tests

This table reports on how diversity in an inventor team's cultural origins (namely *Team cultural similarity*) affects the type of input information utilized by inventor teams in their innovation production activities as well the number of subsequent patents produced by an inventor team in the initial few years after the team's first patent together (see equation (5) in Section 6.1 and equation (6) in Section 6.2 for further details). The dependent variables in columns (1) to (4) are *Team average new cite ratio*, *Percentage of back cites to 'new' foreign patents*, *Percentage of back cites to 'new' other references, and Percentage of back cites to 'new' mature U.S. patents*, respectively. The dependent variables in columns (5), (6) and (7) are the natural log of one plus the number of patents produced by a team in the one year, two year or three year period after the team's first patent together, respectively. *Size of team's total existing knowledge base across all information sources* is the natural log of one plus the number of U.S. patents, foreign patents, and other references in the team's existing knowledge base. *Degree of focus on exploitative innovation by team's first joint patent* equals the natural log of one plus the number of total backward citations to U.S. patents, foreign patents, and other references by the focal team's first joint patent together. As outlined in Section 3.3, we include several sets of control variables for the size (and diversity) of a team's knowledge base, the amount (and diversity) of team members' skills, and the amount (and diversity) of experience accumulated by team members, as well as other controls (team size and team geographic diversity). See Appendix A for definitions of all variables used in this analysis. All regression specifications include Firm × Year fixed effects. Robust standard errors (clustered at the team level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Table 8: Heterogeneous treatment effects around co-inventor deaths (treated teams only) – Inclusion of additional diversity controls

This table reports the change in innovative output for treated teams only around the death of a co-inventor (see equation (4) in Section 5.2.4 for further details). *After*$_{i,t}$ is an indicator equal to one for all years after the focal co-inventor's death and zero otherwise. *Team cultural similarity change*$_i$ equals the surviving team's cultural similarity post the focal co-inventor's death minus the pre-death/pre-treatment team's cultural similarity. The innovation outcome measures are: (1) *Ln(1+Total patents)*; (2) *Ln(1+Average forward citations per patent)*; (3) *Ln(1+Top 10% cited patents)*; (4) *Ln(1+Average backward citations per patent)*; (5) *Average firm self-cite ratio per patent*; and (6) *Ln(1+Total citation-weighted patents)*. *Team immigrant similarity change*$_i$ is a continuous variable equal to the surviving team's immigrant similarity post the focal co-inventor's death minus the pre-treatment team's immigrant similarity. *Team gender similarity change*$_i$ is a continuous variable equal to the surviving team's gender similarity post the focal co-inventor's death minus the pre-treatment team's gender similarity. *Team age similarity change*$_i$ is a continuous variable equal to the surviving team's age similarity post the focal co-inventor's death minus the pre-treatment team's age similarity. Controls for diversity of a team's knowledge base comprise *Team technical knowledge overlap, Team text-based knowledge proximity*, and the standard deviation of team members' *Individual technical knowledge bases*. Controls for diversity in skill of team's inventors comprise the standard deviation of team members' *Total patents to date* and *Average forward cites to date per patent*. Controls for diversity of inventor experience comprise the standard deviation of team members' *Years of inventor experience* and *Average back cites per patent*. We continue to include several sets of control variables for the size of a team's knowledge base, the amount of team members' skills, and the amount of experience accumulated by team members, as well as other controls (team size and team geographic diversity). See Section 3.3.3 and Appendix A for the definitions of all variables used in this analysis. All regression specifications include Individual dead co-inventor fixed effects, Team fixed effects and Year fixed effects. Robust standard errors (clustered at the team level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively. We report normalized coefficients in this Table for ease of comparison and interpretation.

Figure 1: Assessment of parallel trends assumption for triple differences-in-differences analysis

This figure plots the coefficients (and 95% confidence intervals) on the triple interaction term *{Year relative to death$_{i,t}$} × Treated team$_i$ × Team cultural similarity change$_i$* from 3 years prior to 5+ years post the focal co-inventor death (estimated based on equation (3) as described in Section 5.2.1).

Appendix A: Variable definitions

Variable	Description
Panel A: Individual inventor and inventor team innovation output	
Total patents	The number of patents filed (and subsequently granted) in a given year.
Average forward cites per patent	The mean of the scaled forward citations of each patent applied for (and subsequently granted) in that year. Scaled forward citations is calculated as the number of citations that a patent receives divided by the average number of citations made to patents applied for in the same year and CPC technology sub-class. We scale raw citation counts to account for variation in citation rates over time and across technologies as well as address truncation bias that results in patents granted towards the end of the sample having less time to garner citations (Hall, Jaffe, and Trajtenberg, 2001). We form the team-year level measure by calculating the average scaled forward citations across all the team's patents applied for in that year.
Top 10% cited patents	A patent is classed as a top 10% cited patent if it receives citations from other patents that place the focal patent in the top decile of patents in the same application year and CPC technology sub-class.
Average backward cites per patent	The average of the scaled backward citations of each patent applied for (and subsequently granted) in that year. Scaled backward cites equals the number of citations made by the focal patent divided by the average backward citations made by patents applied for in the same year and CPC sub-class.
Average firm self-cite ratio per patent	The 'firm self-cite ratio' for each patent equals the number of backward citations to U.S. patents developed/owned by the team's corporate employer firm, divided by the total number of backward citations to U.S. patents. We then calculate the 'average firm self-cite ratio' across all patents developed by the inventor team each year.
Total citation-weighted patents	The total sum of each granted patent (if any) multiplied by that patent's scaled forward citations, following Kogan et al. (2017).
Panel B: Individual inventor and inventor team characteristics	
Total patents to date	A count of the number of patents granted to an inventor over their career up to the focal year.
Years of inventor experience to date	The number of years between the application date of the first (subsequently granted) patent that an inventor ever applies for and the current focal year.
Individual technical knowledge base	A count of the number of distinct CPC technology sub-classes that an inventor patents in over the course of their career up to the focal year.
Top 10% inventor	An indicator equal to one for inventors whose total patents developed to date place them in the top decile of all inventors in the USPTO universe and zero otherwise.
Average backward cites per patent	Equals the mean of the scaled backward citations made across all the patents developed over an inventor's career up to the focal year.
Average forward cites per patent	Equals the mean of the scaled forward citations received up until (and including) year $t-1$ across all the patents developed over an inventor's career to date.
Panel C: Pairwise inventor characteristics for selection tests	
Co-inventor cultural similarity	Calculated as –1 multiplied by the Euclidean pairwise distance between inventors' cultural values based on Hofstede's framework, where pairwise distance is calculated using the following formula: $Pairwise\ distance_{ij} = [(IDV_{Inventor\ i} - IDV_{Inventor\ j})^2 + (PDI_{Inventor\ i} - PDI_{Inventor\ j})^2 + (UAI_{Inventor\ i} - UAI_{Inventor\ j})^2 + (MAS_{Inventor\ i} - MAS_{Inventor\ j})^2 + (LTO_{Inventor\ i} - LTO_{Inventor\ j})^2 + (IVR_{Inventori} - IVR_{Inventor\ j})^2]^{\frac{1}{2}}$ This measure is transformed so that its values are bound between zero and one, where higher values indicate a higher degree of cultural similarity between inventor i and inventor j. See Section 2.3.2 and Internet Appendices IA.1 and IA.2 for more details.

Variable	Description
Panel C: Pairwise inventor characteristics for selection tests (cont.)	
Co-inventor geographic distance	Natural log of the geodetic distance in miles between the two inventors' then current locations (where inventor locations are identified from patent filings).
Co-inventor difference in average forward cites to date per patent	Equals the absolute difference between each inventor's average forward cites to date per patent. Average forward cites to date per patent equals the mean of the scaled forward citations received across all the inventor's patents to date.
Both top 10% inventors	A dummy variable equal to one when both inventors classify as top 10% inventors.
Co-inventor technological proximity	Cosine similarity measure of the degree of overlap in CPC patent technology sub-classes between patents that are applied for (and subsequently granted) to inventor 1 up to and including year $t-1$ and the similarly defined patents of inventor 2 up to and including year $t-1$. This tech proximity measure is bound between 0 and 1.
Co-inventor difference in average backward cites per patent	Equals the absolute difference between each inventor's average backward cites per patent. Average backward cites per patent equals the mean of the scaled back cites received across all the inventor's patents to date.
Co-inventor difference in years of inventor experience to date	The absolute difference between each inventor's years of inventor experience to date. Years of inventor experience equals the number of years between the application date of the first (granted) patent that an inventor ever applies for and the current year.
Both have 5+ years of tenure at the focal firm	A dummy variable equal to one when both inventors have a tenure of over 5 years at the focal U.S. public firm, and zero otherwise. The tenure of an inventor at a firm is the number of years between the application date of the first (granted) patent that an inventor applies for while working at the focal employer and the current year.
Panel D: Inventor team control variables for treatment and mechanisms tests	
Team cultural similarity	To measure cultural similarity within a team of N inventors, we compute the average of pairwise distances in all pairs of team members using the formula: $$-1 \times \frac{\sum_{i,j} Pairwise\ distance_{ij}}{\frac{N(N-1)}{2}} \quad \forall i < j$$ where $Pairwise\ distance_{ij}$ is the distance between each pair of inventors (i, j). The measure of team cultural similarity is transformed so that its values are bound between zero and one, where higher values indicate higher cultural similarity or less cultural diversity. See Section 3.3.2 and Appendices IA.1 and IA.2 for further details.
Controls for the size and the diversity of the inventor team's initial knowledge base	
Scope of team technical knowledge	Count of distinct CPC sub-classes that at least one team member has patented in prior to year *t* (or number of unique tech classes covered by team's collective prior patents)
Team technical knowledge overlap	The overall team-level average of each pairwise *Co-inventor technological proximity* value (based on each pair of inventor's patents to date). It is bound between 0 and 1.
Team text-based knowledge proximity	The team-level average of each pairwise, cosine similarity between the knowledge in word space of each pair of inventors in the R&D team, based on the patent text vector space model of Whalen et al. (2020) and all patents successfully applied for by each pair of co-inventors up to year $t-1$. It is bound between 0 and 1.
Team average of individual technical knowledge bases	Average of each team member's tech class experience to date (based on the number of distinct CPC sub-classes that an inventor patents in over their career to date).
Team diversity in individual technical knowledge bases	The standard deviation in the technology class experience/individual technical knowledge bases of each team member to date.
Controls for the amount and diversity of an inventor team's skill	
Team average total number of patents to date	The average of each team member's total number of (eventually granted) patents filed to date.
Team diversity in total number of patents to date	The standard deviation in the total number of patents developed by each team member to date.

Variable	Description
Panel D: Inventor team control variables for treatment and mechanisms tests (cont.)	
Controls for the amount and diversity of an inventor team's skill (cont.)	
Team average forward citations to date per patent	The average of each team member's average forward citations to date per patent.
Team diversity in average forward citations to date	The standard deviation in the average forward citations to date per patent of each team member.
Controls for the amount and diversity of an inventor team's experience	
Team average inventor experience to date	The average of each team member's inventor experience to date.
Team diversity in inventor experience to date	The standard deviation in the inventor experience acquired by each team member to date.
Team average backward citations per patent	The average of each team member's average backward citations per patent.
Team diversity in average backward citations	The standard deviation in the average backward citations per patent of each team member.
Other controls	
Team size	The number of inventors in the focal inventor team.
Team geographic diversity	The average of the pairwise co-inventor geographic distances between all members of the inventor team.
Team's total existing knowledge base in year t	The combination of every U.S. patent, foreign patent, or other reference material that has been previously cited or created by at least one team member prior to year t.
Scope of team's existing knowledge base across all information sources	The natural log of one plus the team's total existing knowledge base in year t.
Degree of focus on exploitative innovation by team's first joint patent	The natural log of one plus the number of total backward citations made by the team's first joint patent together to U.S. patents, foreign patents, *and* other references.
Panel E: Intermediate mechanism-related outcome variables	
Team average new cite ratio	The average 'new cite ratio' across all patents ever developed by an inventor team, where each patent's new cite ratio equals the total number of backward cites to 'new knowledge' (i.e., cites to U.S. patents, foreign patents, or 'other references' that are outside of the team's 'existing knowledge base') divided by the total number of backward citations made to U.S. patents, foreign patents and 'other references'.
Percentage (%) of back cites to 'new' foreign patents	The team-level average of the ratio of all backward citations on team patents to 'new' foreign patents (i.e., cites to foreign patents that are outside of the team's existing knowledge base) divided by the total number of backward citations to any source.
Percentage (%) of back cites to 'new' other references	The team-level average of the ratio of all backward citations on team patents to 'new' other references (i.e., cites to other references that are outside of the team's existing knowledge base) divided by the total number of backward citations to any source.
Percentage (%) of back cites to 'new' mature U.S. patents	The team-level average of the ratio of all backward citations on team patents to 'new' mature U.S. patents (i.e., cites to U.S. patents that are aged 10 years or older that are outside of the team's existing knowledge base) divided by the total number of backward citations to any source.
Number of team patents within 1/2/3 year(s) after first patent together	The natural logarithm of one plus the number of (eventually granted) patents applied for by the focal team within the one-, two-, or three-year period after the application date of the focal team's first patent together.

The Internet Appendix of

"SHARED CULTURE AND TECHNOLOGICAL INNOVATION: EVIDENCE FROM CORPORATE R&D TEAMS"

Appendix IA.1: Procedure to Trace Inventors' Family Trees

To determine an inventor's inherited cultural values, we identify all relatives from each inventor's family tree using the following eight-step procedure.

Step 1. We match inventors in the patent database to individuals in the Infutor database as follows:

i. Matches are performed based on first name, middle name, last name, gender, city, and state of residence. We require that all cities and states associated with the inventor are matched with residence locations in Infutor.

ii. To facilitate more accurate matches, we correct for spelling errors in names and standardize city names using USPS standard city names prior to matching.

iii. For female inventors, we also use alternative last names (i.e., maiden names) provided by Infutor for matching.

iv. If multiple matches are found for an inventor, we include an additional restriction that the patent application year is between the starting and ending address years in Infutor while allowing plus or minus one year.

v. If no matches are found from Step 1(i), we relax some conditions including:

    1. Instead of requiring non-missing middle names, we allow for matches with non-conflicting middle names (i.e., one middle name is missing or both middle names are missing).

    2. Instead of requiring a match on all cities and states in which an inventor is located at the time of patenting, we require matching of at least one set of city and state between the patent data and the Infutor data.

3. Instead of requiring perfect matching of first and last names, we accommodate variations of first names such as nick names and allow for small errors between names (e.g., one letter difference).

vi. We uniquely matched 1.1 million inventors using Infutor data, which represents 73% of the 1.5 million U.S.-based inventors (including those that work in both private and public companies) that patented between 1981 and 2016.

Step 2. Using the Infutor database, we find older relatives of the matched 1.1 million inventors from Step 1 as follows:

i. Older relatives are defined as household members who were born before the inventors and who were residing at the same household at the same time sharing the same last names as the inventors. We require same last names to prevent matching with unrelated individuals such as roommates.

ii. We use inventors' last names and alternative last names (i.e., maiden names) to capture relatives on both the father's side and the mother's side.[58]

iii. We perform three iterations of matching to obtain multiple generations of relatives.[59] This step produces 8.3 million matched relatives.

Step 3. To supplement the list of relatives from Infutor and to establish whether a deceased inventor satisfies our treatment sample inclusion requirements detailed in Section 5.2.1, we manually search for 5,647 deceased inventors in the LexisNexis Public Records

[58] For example, if Mary Smith changed her name to Mary Johnson after marriage, then when we track Mary Smith's residences going back in history, we would be able to capture Mary Smith's relatives using household members sharing the same last name "Smith".

[59] Unlike Census data, it is not possible to perfectly identify parents, grandparents, and great grandparents of inventors in Infutor without information on relationship between household members (e.g., relatives can be older siblings, uncles, and aunts living in the same household). Whenever possible, we use age and information on parents from BUNMD to identify direct relatives and drop other relatives such as siblings, uncles, and aunts.

database. LexisNexis provides demographic information and identifies potential relatives based on household members at individuals' current and past residences. We first manually search for these inventors in LexisNexis using their names and locations (inventor city and state from the patent database) and use provided information on employment history, business associates, education, and email addresses to identify the correct LexisNexis record. For each inventor and the associated list of potential relatives, we save their demographic information including names, alternative names, year and month of birth, and the first five digits of social security number.

Step 4. We match inventors and their relatives from Steps 1 to 3 to the Berkeley Unified Numident Mortality Database (BUNMD) based on first name, middle name, last name, and the first five digits of their social security number. BUNMD covers more than 49 million death records from 1988 to 2005 and contains information that Infutor does not have such as individuals' place of birth, names of parents, and race. After matching inventors and their relatives from Infutor to BUNMD, we obtain 37,567 unique individuals who were born in a foreign country. These foreign-born persons are saved and further processed in Step 8.

Step 5. We drop the matched inventors and relatives (from Steps 1 to 3) who were born after 1940 or identified as foreign-born from Step 4, which yields 1.2 million individuals. Around 45% of the matched inventors from Step 1 have at least one relative who was born in 1940 or earlier. For the 1.2 million matched inventors and relatives who were born in 1940 or earlier, we match them to the full-count 1940 U.S. Census database as follows:

i. For around 20% of the sample with BUNMD information, we match these individuals to Census records based on first name, middle name, last name, gender, birth year, birthplace, race, and names of parents. For each individual, we keep the best match.

ii. For the remaining sample without BUNMD information, we match these individuals to Census records based on first name, middle name, last name, gender, birth year, and SSN issue state. We match SSN issue state from Infutor to state of birth or state of residence in the 1940 Census.[60] For each individual, we keep the best match.

iii. Of the 1.2 million inventors and relatives, 855,941 (71%) of them are matched to the 1940 Census database. For these individuals, we find all members of their households and only keep the individuals themselves, their parents, and grandparents on both the father's side and the mother's side. We identify parents and grandparents based on relationship information provided in the 1940 Census. This process yields 4.14 million unique Census household members.

iv. We do not need to match a 1940 Census household member with earlier Census records if the member was foreign-born or both of his or her parents were foreign-born. This applies to 414,417 unique 1940 Census household members, which we save and further process in Step 8. For the remaining 3.7 million 1940 Census household members, we keep tracing the ancestry origin for them using the 1930 Census database.

Step 6. We match the 3.7 million 1940 Census household members from Step 5 to the 1930 U.S. Census database using last name, middle name, first name, gender, race, birthplace, birth year, mother's birthplace, and father's birthplace. For the individuals matched to the 1930

[60] For reference, using BUNDMD data, we find that the SSN issue state is the same as the state of birth in 78% of cases.

Census database, we find all members of their households and only keep the individuals themselves, their parents, and grandparents on both the father's side and the mother's side. We identify parents and grandparents based on relationship information provided in the 1930 Census. Like the previous step, we save household members who were foreign-born or both of their parents were foreign-born in a separate file, and keep tracing the ancestry origin for the remaining household members using the 1920 census dataset.

Step 7. We repeat Step 6 for 1920, 1910, 1900, 1880, 1870, 1860, and 1850 full count Census datasets. After each iteration of matching is completed, we save the foreign-born matched household members and keep the remaining U.S.-born household members for the next round of matching.

Step 8. We collect all the foreign-born household members from the matched 1850 to 1940 Census datasets from Steps 5 to 7, which yields 2.9 million individuals who were foreign-born, or both of their parents were foreign-born. These individuals are combined with the 37,567 foreign-born individuals identified using BUNMD from Step 4. Using the country of birth information on these foreign-born individuals from inventors' family trees, we define cultural values for each inventor as follows:

i. If the inventor was born in a foreign country, we define the country of birth as the inventor's country of origin and use the six-dimension Hofstede cultural values in that country as the inventor's inherited cultural values.

ii. If the inventor was not born in a foreign country and the inventor has at least one matched foreign-born relative, then for each of the six Hofstede cultural dimensions, we take the

average values across all the foreign-born relatives of the inventor.[61] We use these averaged Hofstede cultural values as the inventor's inherited cultural values.

iii. Using the method above, we obtain inherited cultural values for 322,687 unique inventors, which represents around 30% of the matched 1.1 million inventors from Step 1 and around 22% of 1.5 million U.S. inventors that patented between 1981 and 2016.

[61] For robustness, we also used a weighted average measure that gives a higher weight to relatives closer to the inventor in the family tree. We obtain very similar results using this alternative measure.

Appendix IA.2: Procedure to Determine Inventors' Countries of Origin and Inherited Cultural Values

We use a novel, multi-layered approach to identify inventors' countries of origin and determine their inherited cultural values.

Step 1. We use Infutor's Consumer History Plus (CRD4) database, LexisNexis Public Records, Berkeley Unified Numident Mortality Database (BUNMD), and the restricted full count U.S. Census records from 1850 to 1940 from the Minnesota Population Center to track down relatives from each inventor's family tree to determine the inventor's inherited cultural values based on exact countries of ancestry. Using the procedure described in Appendix IA.1, we obtain inherited cultural values based on all relatives' exact country of ancestry for 322,687 unique inventors.

Step 2. To supplement precisely determined countries of ancestry from Step 1, we manually search for inventors and determine their countries of origin for the 4,000 most productive inventors who are not matched from step 1. For these inventors, we search by hand using LinkedIn and other biographical resources such as the Marquis Who's Who database, corporate web profiles and Wikipedia. Using available information on country of birth, parents' country of birth, location of their high school or bachelor granting institution, languages spoken, and pictures, we are able to determine the country of origin for 2,013 inventors.

Step 3. For the inventors that are matched to the Infutor database from Step 1 of the procedure described in Appendix IA.1 that do not yet have inherited cultural values, we identify

inventors who are first-generation immigrants as individuals who are more than 20 years old when assigned a social security number (SSN) following Bernstein et al. (2022).

i. To estimate when inventors received their SSN, we decode SSN provided in Infutor using https://www.ssn-verify.com, which provides information on the issue state, the first year and last year issued for each set of five-digit social security number. These first-generation immigrant inventors account for about 16% of total inventors.

ii. Since most of these inventors (and their relatives) will not be in the 1850 to 1940 U.S. Census records, we determine their country of origin based on their surnames using several public and commercial sources that are more suitable for more recent immigrants:[62] Specifically, we use four sources: Nationalize.io (https://nationalize.io), Forebears (https://forebears.io), NamePrism (https://www.name-prism.com), and Dictionary of American Family Names from Oxford Reference. For each inventor, we find the most likely country of origin according to each of the four sources based on the inventor's surname and a match is recorded if the most likely country of origin appears in two or more sources.[63]

Step 4. For the remaining inventors who are most likely U.S.-born second or higher generation immigrants, we identify their countries of ancestry based on their surnames using the 1850 to 1940 U.S. Census records, following the methodology of Liu (2016). For female inventors, we use their maiden names provided by Infutor for matching to maximize accuracy whenever possible. We use U.S. Census records for these inventors because

[62] According to the Pew Research Center (2015), immigrants that entered the U.S. during the latest wave of immigration post-1965 mostly come from Latin America and Asia countries. The top three source countries are Mexico, China, and India.

[63] For robustness, we use both first names and last names for matching, and we also use weighted percentage of countries instead of the most likely country of origin and obtain similar results.

they likely have relatives in the 1850 to 1940 U.S. Census. However, we are not able to track their family trees directly using the procedure described in Appendix IA.1 because we cannot find a relative for them who was born in 1940 or earlier using Infutor or LexisNexis, which has better coverage for individuals born in more recent decades. Essentially, instead of tracking down direct relatives from inventors' family trees as in Appendix IA.1, we find all possible relatives for these inventors as individuals who share the same surnames using U.S. Census records as follows:

i. We use U.S. Census records from 1850 to 1940 to identify each inventor's country of origin based on all possible relatives sharing the same surname. Specifically, we restrict the dataset to first- and second-generation immigrants whose country of birth or father's country of birth is outside of the United States. We then link each unique surname from the Census records to its most frequently associated country of birth or father's country of birth. For instance, the surname "Wong" is linked to China because 97.2% of immigrants with the same surname are from China. To further verify these matches, we also use the surname-ancestry country matching list from a commercial database, Origins Info Ltd., which is a well-known commercial vendor of name classification services. Origins Info processed the list of surnames using its proprietary database constructed based on sources such as the American Dictionary of Family names and international telephone directories. The accuracy of Origins Info's matching has been validated in prior studies (Webber, 2007).

ii. To create the final matching list, we do the following.

    1. First, we record matches where the most frequently associated country of birth from census records is the same country of origin identified by Origin Info.

2. Second, we keep surnames for which the most frequently associated country of birth appears in more than 75% of the census records.
3. Third, for surnames with different census and Origin Info country of origin, we hand-check their country of origin using sources such as dictionaries and ancestry.com, which provides a distribution of U.S. immigrants based on port entry records. We record a match if at least two sources agree on the country of origin for a surname.
4. Fourth, for the remaining unmatched surnames, we hand-check their country of origin using sources such as dictionaries and ancestry.com for 3,000 of the most common surnames. The procedure generates a list of over 1.5 million unique surnames and their associated country of origin. Finally, we merge the surname data with remaining inventors from the patent database.

Step 5. For inventors who are not matched in Step 1, we define the inventor's inherited cultural values as the six-dimension Hofstede cultural values in the country of origin as determined by Steps 2 to 4. Combined with the 322,687 inventors from Step 1, we obtain inherited cultural values for about 98% of 1.5 million U.S.-based inventors (including those working in both private and public companies) that patented between 1981 and 2016.

Appendix IA.3: Survey-based validation of culture measures

To further validate the underlying assumption of our culture measures, we empirically test the relation between the Hofstede cultural values in an individual's country of ancestry and the individual's personal beliefs using individual responses to relevant survey questions from the 1972 to 2016 sample of the U.S. General Social Survey. The survey, which is frequently used in the economics literature, asks respondents in the U.S. their background information and their opinions on a wide array of topics. To identify ancestry background, we use responses to the question: "from what countries or part of the world did your ancestors come?" Based on these responses, we construct individual-level Hofstede cultural measures analogous to the main cultural measures used in the empirical analysis for inventors. We then conduct individual-level regressions where the dependent variables are respondents' responses to survey questions relating to each of the six Hofstede cultural dimensions and the independent variables are the Hofstede cultural measures in the respondents' reported countries of ancestry and a set of individual-level controls.

The survey questions that we select for each Hofstede cultural dimension are as follows. For the individualism dimension, the selected question asks respondents to pick what quality that they think is most important to teach their children to prepare them for adulthood, where 'to think for himself or herself' is one of the possible qualities. For the power distance dimension, the selected question asks whether people should obey the law without exception or follow their consciences, which is closely related to the concept that people in high PDI societies obey authority without questioning it. For the uncertainty avoidance dimension, we select questions related to people's preference for a job that has no danger of being fired, which is related with the idea that people in high UAI societies prefer certainty. For the masculinity dimension, we select questions related to people's views on traditional gender roles and gender inequality. For the long-term orientation

dimension, we infer time orientation based on smoking status since smoking generates short-term pleasure but has known long-term negative health consequences. For the indulgence dimension, we select questions related to exercising restraint (which is the opposite of indulgence) such as the importance of having self-control and working hard.

In column (1) of Table IA.1, we focus on the individualism dimension and find that U.S. respondents from ancestry countries with higher individualism scores think it is more important to teach children to think for themselves to prepare them for life as an adult. This result is in line with the notion that people in more individualist societies are expected to take care of only themselves and their immediate families. In columns (2) to (6) of Table IA.1, we examine the other five Hofstede dimensions in a similar way and find that the Hofstede cultural values in a respondent's country of ancestry are strongly related to the respondent's individual views on related issues.

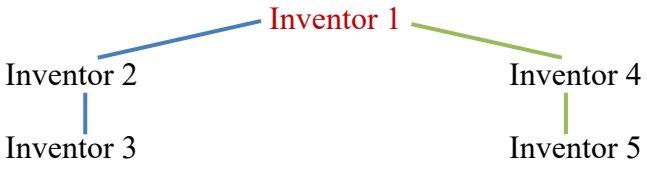

Overall, these results provide empirical support for the underlying premise of our measures of inherited cultural values that inventors' cultural heritage, as measured by the prevalent preferences in their country of ancestry, significantly impacts their values and preferences. This supports the idea that inventors sharing similar cultural backgrounds tend to have more similar values compared to inventors from different cultural backgrounds. In addition, since more than 90% of the respondents are second or higher generation immigrants, these empirical results also lend support to the idea that immigrant cultures are persistent across generations. The notion that immigrants bring their cultural beliefs to the new host country and pass down these beliefs to their descendants resulting in the persistence of cultural beliefs across generations has been empirically demonstrated by many studies in the economics literature (e.g., Guiso, Sapienza, and Zingales, 2006; Fernández and Fogli, 2009; Fernández, 2011).[64]

[64] For more evidence on the persistent intergenerational transmission of cultural beliefs, see Bisin and Verdier (2011).

Appendix IA.4: Additional explanation of how our difference-in-differences methodology controls for the *relative* contribution of each deceased inventor to each of their specific teams

As explained in Section 5.2, our empirical procedure specifies that every comparison of inventor teams in our treatment tests involves comparing two inventor teams that operate *within the same firm* at the *same point in time*. In conjunction with Team and Year fixed effects, this setup ensures that our treatment test results cannot be explained by factors across firms or time-invariant team and year effects.

Importantly, our inclusion of various (time-varying) control variables that capture the amount and diversity of knowledge, skills, and experiences of each inventor team also allows us to *explicitly control for the relative contribution of the deceased co-inventor to each of their treated teams*. This includes cases where the focal deceased inventor is the same person for two sets of treated teams in our most restrictive treatment effects analysis implemented in Section 5.2.4. As illustrated in the example below, this identification strategy focuses on comparing sets of treated teams who experience the *loss of the exact same co-inventor* (i.e., Inventor 1 in the illustrative example below) while working at the same firm (through the inclusion of Dead co-inventor fixed effects):

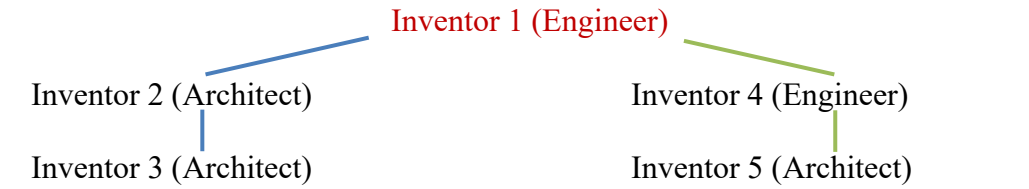

Treated Team A (*pre-death*)
= Inventor 1
+ Inventor 2
+ Inventor 3

Treated Team B (*pre-death*)
= Inventor 1
+ Inventor 4
+ Inventor 5

Treated Team A (*post-death*)
= Inventor 2
+ Inventor 3

Treated Team B (*post-death*)
= Inventor 4
+ Inventor 5

For example, assume that the treated teams A and B are both focused on developing building/ construction-related technologies for the same corporate employer. Assume that Team A has one engineer (Inventor 1) and two architects (Inventor 2 and Inventor 3) while Team B has two engineers (Inventor 1 and Inventor 4) and one architect (Inventor 5). The two teams share the same engineer (Inventor 1), who passes away unexpectedly.

Treated Team A (*pre-death*)
= Inventor 1 (Engineer)
+ Inventor 2 (Architect)
+ Inventor 3 (Architect)

Treated Team B (*pre-death*)
= Inventor 1 (Engineer)
+ Inventor 4 (Engineer)
+ Inventor 5 (Architect)

Treated Team A (*post-death*)
= Inventor 2 (Architect)
+ Inventor 3 (Architect)

Treated Team B (*post-death*)
= Inventor 4 (Engineer)
+ Inventor 5 (Architect)

Inventor 1's death will arguably have a larger effect on Team A than Team B because Inventor 1 was the only engineer on Team A and thus less replaceable. In other words, the deceased Inventor 1 may have a higher team-specific value-add to Team A than Team B. As such, it is possible that Team B will subsequently outperform Team A while it is also possible that Team B just so happens to be the team that experiences an increase in team cultural diversity (this possibility is hereafter referred to as the "alternative hypothesis").

Before continuing, it is important to note that our extensive univariate comparisons of observable characteristics between our two sets of treated teams in Panels D, E, and F of Table 4 indicate that our heterogenous treatment effects sample is quite well balanced with no systematic correlation between changes in team cultural value diversity and changes in the team's base of knowledge, skills, and experiences. For example, we show in Panel E of Table 4 that the *Percentage*

of unique tech class knowledge lost due to the focal co-inventor's death as well as the *Change in team technical knowledge overlap due to co-inventor death* and the *Change in team text-based knowledge proximity due to co-inventor death* are insignificantly different between treated teams whose cultural value similarity increases post-death vs. treated teams whose cultural similarity does not increase post-death. The comparability of our treated teams, in terms of team patenting output, is further confirmed by Panel C of Table 4 and unreported parallel trends tests.

Nevertheless, a critical benefit of our heterogenous treatment effects specification with dead co-inventor fixed effects is that the relatively higher contribution of Inventor 1 to Team A as opposed to Team B in our hypothetical example above will naturally be accounted for as part of the change in our multitude of control variables that capture the amount and diversity of knowledge, skills, and experiences possessed by the focal inventor team in each year. This can be seen in the continuation of our stylized example:

Treated Team A (*pre*-Inventor 1 death)				**Treated Team B (*pre*-Inventor 1 death)**			
Control variable	Inventor background	Tech classes patented in	Scope of team knowledge base	Control variable	Inventor background	Tech classes patented in	Scope of team knowledge base
Inventor 1	Engineer	K,L,M		Inventor 1	Engineer	K,L,M	
Inventor 2	Architect	X,Y,Z		Inventor 4	Engineer	K,L,M	
Inventor 3	Architect	X,Y,Z		Inventor 5	Architect	X,Y,Z	
Team A control value (pre-death)			**6**	**Team B control value (pre-death)**			**6**
Treated Team A (*post*-Inventor 1 death)				**Treated Team B (*post*-Inventor 1 death)**			
Control variable	Inventor background	Tech classes patented in	Scope of team knowledge base	Control variable	Inventor background	Tech classes patented in	Scope of team knowledge base
Inventor 2	Architect	X,Y,Z		Inventor 4	Engineer	K,L,M	
Inventor 3	Architect	X,Y,Z		Inventor 5	Architect	X,Y,Z	
Team A control value (post-death)			**3**	**Team B control value (post-death)**			**6**
Change in Team A control value			**–3 (–50%)**	**Change in Team B control value**			**0 (0%)**

Note: Team A (or B) control value refers to the value of the control variable, *Scope of team knowledge base*, which is the count of unique technology classes that any team member has previously patented in up to the focal analysis year. Change in Team control value = Team control value (post-death) – Team control value (pre-death).

For example, if Inventor 1's contribution of unique technical knowledge is relatively higher for Team A than Team B, then the decline in the control variable *Scope of team technical knowledge* (which counts the number of unique technology classes that any team member has previously patented in) will be relatively greater for Team A than Team B. This same logic can be applied for our full set of extensive, time-varying control variables capturing the amount and diversity of each inventor team's knowledge, skills, and experiences.

Since we also include Team FEs in our within-firm diff-in-diff specification to control for time-invariant components of a team's knowledge, skills, and experiences, we explicitly control for both the time-varying *and* the time-invariant components of knowledge, skills, and experiences provided by the same surviving inventors in both the pre- and post-death period. This leaves the *relative* contribution (or loss) of the deceased inventor's knowledge, skill, and experience between the pre-death period and the post-death period as the primary driver of changes in team-level control variables. As such, our coefficient estimates for the effect of team cultural similarity on team output are already conditional on the relative importance of the dead inventor's knowledge, skill, and experience to each treated team of which they were a member.

Therefore, our treatment effects specifications can control for the possibility that the same co-inventor's death can impact different teams differently due to a deceased co-inventor's team-specific value-add. This in turn allows us to generate credibly causal estimates of the incremental impact of team cultural diversity on team innovation output.

Finally, in the hypothetical scenario outlined above, one would expect that Team B (assuming for illustrative purposes that the team's cultural similarity decreases post Inventor 1's death) would clearly and uniformly outperform Team A (assuming for illustrative purposes that the team's cultural similarity increases post Inventor 1's death) in the post-treatment period. However, we find

that overall (citation-weighted) patent output is *not* significantly different in the post-treatment period between the two sets of treated teams but that only the type and distribution of team innovation outcomes significantly change. In other words, treated teams that become more culturally homogenous produce a higher overall quantity of patents that are more exploitative in nature while treated teams that become more culturally diverse produce more risky, exploratory patents with a greater potential for high-impact innovations. As such, our unique distributional results concerning both the positive and negative effects of team cultural value diversity on team innovation output do not appear to be logically consistent with the predictions of the alternative hypothesis. Specifically, in the hypothetical scenario above, our main empirical results would indicate that Team A outperforms Team B in terms of the quantity of patents produced while the overall (citation-weighted) patent outputs of Teams A and B do not significantly differ, which are inconsistent with the prediction of the alternative hypothesis that Team B would uniformly outperform Team A across all innovation output metrics in the post-treatment period.

Appendix IA.5: Procedure to Identify Treated and Control Teams in Diff-in-Diff Tests

The first step in implementing our triple difference-in-differences empirical strategy involves identifying active inventor teams at U.S. publicly listed firms that experience the 'premature' death of one of their team members (otherwise referred to as the "treated teams"). We begin with USPTO data and reports that directly identify inventors who died around the date of patent application.[65] We then supplement and match this information with Infutor's Consumer History Plus (CRD4) database, LexisNexis Public Records, and the Fold3 Social Security Death Index to identify those deceased inventors that:

a) Died between 1981 and 2011 (ensures we have at least 5 years of pre- and post-death data);

b) Are employed at a U.S. publicly listed firm at the time of their death; and

c) Are no older than 60 years of age at the time of their death.[66]

Next, to isolate 'active' inventor teams that are likely to be genuinely impacted by the death of their colleague, we identify all teams of 3+ inventors[67] that collaborated with the deceased inventor (at the same firm) on a patent that was applied for within 3 years of the focal inventor's death.[68] Finally, we require that we have data on each team member's cultural heritage, location, and patenting history. These filters ultimately result in the identification of 2,637 treated teams that were actively collaborating at a U.S. public firm around the date of a co-worker's premature death.

[65] In the inventor fields published on the USPTO website, a recently deceased inventor will have a 'deceased' or 'late' label affixed to their name and/or have their legal representative noted on the patent application. Separately, the USPTO publishes records of petitions related to deceased inventors and their patent applications. A key advantage of relying directly on this USPTO data is that it more precisely identifies the deceased inventor's name, location, and employer at time of death. This helps facilitate matching a deceased inventor's patenting history to their personal characteristics.
[66] Following Jaravel et al. (2018), we define a 'premature' co-inventor death as an inventor that was 60 years old or younger at the date of their passing to reduce the likelihood that the death is due to a long-standing health condition.
[67] In our main analysis, we exclude original two-person inventor teams (comprising the deceased inventor plus one more surviving inventor) because it is not feasible to calculate meaningful "team-based" diversity measures in the post-treatment period when the surviving treated "team" only comprises one living inventor.
[68] Our empirical results are very similar if we use a 5-year 'active' cut-off threshold instead of 3 years.

The second step in our empirical strategy is to use the following procedure to match each treated team with a corresponding counterfactual control team that does not experience a co-inventor death. First, we identify all teams of inventors working at the same firm as the treated team and keep those teams that have the same number of inventors as the treated team prior to the focal co-inventor's death. Second, we ensure that no members of the potential control team have an existing collaboration with any treated team member in our sample.[69] Third, we require that the potential control team is actively working together around the time of the focal co-inventor's death. Specifically, the control team must have successfully patented together at least once in the 3 years leading up to the focal co-inventor's death. Fourth, we require that the potential control team has developed the same number of (eventually granted) patent applications to date as the treated team at the time of the focal co-inventor's death to ensure that the control team has similar team-specific human capital and productivity as the treated team. Finally, we specify that the chosen control team has the closest proximity to the treated team in terms of cultural value diversity. We then use this control team's characteristics and patenting activity as the counterfactual for how the relevant treated inventor team would have performed if they did not experience the loss of their collaborator. After implementing this procedure, we have a final sample for our triple diff-in-diff analysis of 2,441 treated teams and 2,441 counterfactual controls.[70]

To illustrate our approach, take as an example from our data three inventors (Mr. A, Mr. B, and Mr C.) who are working at the technology firm Z. This team applies for three (eventually granted) patents before the year 2005. We then observe that Mr. A dies before his 60th birthday in

[69] This ensures that control teams are not subject to any direct spill-over effects arising from a colleague's death.
[70] We are not able to find a suitable counterfactual control team for approximately 7% of our sample. This principally occurs in smaller U.S. public firms with a more limited pool of inventors that are unaffiliated with inventors comprising the treated teams. However, in unreported tests, the unmatched treated teams do not appear to be significantly different (at least on observable characteristics) from those that do find a matching control team. Note also that *all* treated teams are included in our most restrictive heterogeneous treatment effects specification outlined in Section 5.2.4.

the year 2005. We would proceed to form a pair of treated and counterfactual control teams related to this co-inventor death as follows. First, we define the post-death treated team as the combination of Mr. B. and Mr. C. and calculate all post-death team-level output and characteristics based on these two surviving individuals. Second, we find a counterfactual control team working at the same firm Z with no connection to any of the treated inventors based on the following criteria:

(1) The control team must have the same number of team members in the pre-treatment period as the treated inventor team (in this case, three individuals);

(2) Control team must be actively collaborating around the time of the co-inventor's death (in this case, the control team must have patented together at least once between 2002 to 2005);

(3) The control team must have generated three (eventually granted) patent applications by the time of the focal co-inventor's death (in this case, 2005); and

(4) The chosen control team is the one closest to the treated team's pre-death cultural values.

Appendix IA.6: Construction of dependent variables used in Section 6 Mechanisms Tests

To test Predictions 1 and 2 in Section 6, we examine whether more culturally diverse teams are more likely to cite 'prior art' in their patent applications that: (a) has *not* been developed or cited by any team member in any of their prior patents (i.e., cites to "new knowledge") and (b) is relatively less proven and/or more distant from established theories in that technology field.

One unique advantage of our setting is that all patent applicants have a "duty of candor and good faith" to disclose all prior arts that are material to the patentability of their applications (37 CFR 1.56). Given the potential adverse consequences of failing to cite key prior arts and that citation lists are reviewed by external USPTO patent examiners, applicants have a strong incentive to properly cite all relevant materials in their USPTO filings (Hirshleifer, Hsu and Li, 2018). As such, we use the prior art cited on the focal patent document as an objective and unbiased proxy for the information set that was in fact used by the team to create the focal patented technology.[71]

New cite ratio (percentage of backward cites to "new knowledge")

To help determine *how much* an inventor team is drawing on novel information sources relative to their pre-existing knowledge base in order to develop their subsequent innovations, we first estimate the total size and composition of the focal team's existing knowledge base each year. For each team patent applied for in year t, we examine every patent co-invented by any team member up to and including year $t-1$ (whether individually or jointly) and record every backward citation made to U.S. patents, foreign patents, or "other references".[72] Analogous to Ma (2020), we estimate an inventor team's existing knowledge base in year t as any U.S. patent, foreign patent, or other references that has been previously cited or created by at least one team member prior to

[71] See Hirshleifer et al. (2018) for further discussion of the reasons why the tendency to 'under-cite' or 'over-cite' is relatively negligible in this setting.

[72] 'Other references' includes all non-patent material that the inventors cite as prior art in their patent application like scientific/academic journal papers, books, trade publications, public/private sector reports and conference proceedings.

year t.[73] A back cite on the focal year t patent to a U.S. patent, foreign patent, or other references that is outside of the team's existing knowledge base is thus classified as a "cite to new knowledge."

We then compute each patent's *New cite ratio* as the total number of cites to new knowledge divided by the total number of backward citations to any information source. Thus, a new cite ratio value closer to one indicates a relatively high reliance on "new-to-the-team" information sources when developing the focal innovation idea while a new cite ratio value closer to zero suggests that the inventor team primarily drew on their pre-existing stock of knowledge when formulating a new patent. Note that our "New cite ratio" measure implicitly controls for the team's general propensity to cite prior art since the denominator of this ratio is total backward cites to any information source.

Percentage of backward cites to 'new' foreign patents, 'new' other references, and 'new' mature U.S. patents (measures of the type and risk profile of input knowledge sources)

To test our second prediction, we assess the *type and risk profile* of input information sources used by inventor teams by categorizing each backward citation that a team makes on the focal patent to "new knowledge" into three categories: (1) cites to 'new' foreign patents, (2) cites to 'new' other (non-patent) references, and (3) cites to 'new' mature U.S. patents (where 'mature' U.S. patents are defined as those granted U.S. patents that were developed at least 10+ years ago).

We argue that a team's greater reliance on foreign patents and other non-patent references as their underlying source of "new-to-the-team" knowledge is significantly riskier (albeit potentially more novel) problem-solving strategy than the use of older 'mature' U.S. patents. Notably, other references are comprised of some resources that are not as commercially focused and technically relevant as U.S. patents. For example, academic publications (that represent the largest proportion of 'other references') are more likely to contain riskier basic research ideas, where there is inherent

[73] Unlike the prior literature, however, our estimate of the 'existing knowledge base' is measured at the team-level (not the firm-level) and we include foreign patents and other references (not just U.S. patent backward citations).

uncertainty in translating academic hypotheses and tests to real-world, commercial applications (Arora, Belenzon, and Sheer, 2021). Similarly, foreign patents granted in overseas jurisdictions tend to be less well known and cited, and thus not as widely used, tested, and advanced upon by subsequent inventors, compared to U.S. issued patents (e.g., Harhoff, Narin, Scherer, and Vopel, 1999). Conversely, a relatively greater reliance on older U.S. patents as the underlying source of new knowledge is consistent with that inventor team's preference to build upon well-established technologies with more proven commercial utility (Mukherjee, Romero, Jones, and Uzzi, 2017).

We hypothesize that more culturally diverse teams will have a relatively:

a) *Higher percentage of back cites to 'new' foreign patents* on the basis that more culturally diverse teams are more likely to have at least one team member that is aware of and willing to rely on technology developed outside of the United States when formulating new ideas
b) *Higher percentage of back cites to 'new' other references* because more culturally diverse teams are more likely to incorporate non-traditional, non-patent materials into the team's innovation search process to help resolve more frequent conflicts in individual perspectives
c) *Lower percentage of back cites to 'new' mature U.S. patents* since less culturally diverse teams, with greater similarity in their problem-solving approaches, may have less incentive to search outside the available bank of directly relevant (commercially and technically) patent-based knowledge, especially more tried and tested 'mature' U.S. patents.

As a final step, we take the average of each of these four $Team\ information\ source\ ratios$ (including *Team average new cite ratio*) across all patents ever developed together by the focal team. By construction, as each team will only have one sample observation, our method implicitly lowers the influence that any team, particularly more productive ones, may have on our estimates.[74]

[74] However, for robustness purposes, we also re-run our analysis at the individual patent level (which implicitly puts more weight on relatively more productive and frequently patenting inventor teams) and obtain very similar results.

Appendix IA.7: Procedure for computing the similarity in the immigrant status, gender, and age of inventor team members

In this Appendix, we provide further details on how we construct our measures of *Team immigrant similarity*, *Team gender similarity*, and *Team age similarity* that we utilize for our robustness tests in Sections 7.2.1 and 7.2.2, respectively.

To construct *Team immigrant similarity*, we first identify the immigrant status of each inventor in the focal team by utilizing the first five digits of social security numbers of the matched inventors in Infutor's Consumer History Plus database. Following Bernstein et al. (2022), we identify inventors who are first-generation immigrants as individuals who are more than 20 years old when assigned a social security number (SSN). To estimate when inventors received their SSN, we decode SSN provided in Infutor using https://www.ssn-verify.com, which provides information on the issue state, the first year and last year issued for each set of five-digit social security number. These first-generation immigrant inventors account for about 16% of all inventors. *Team immigrant similarity* is then calculated as one minus the Blau (1977) immigrant diversity measure, which equals to $2 \times (1 - [(\text{Percent of team that is first-generation immigrant})^2 + (\text{Percent of team that is U.S. native})^2])$. Higher values of *Team immigrant similarity* signify less team immigrant diversity.

To construct *Team gender similarity*, we first identify the gender of each inventor (male or female) in the focal team using three steps. First, we use Infutor's Consumer History Plus database, which contains detailed demographic information including gender. We match inventors in the patent database to individuals in the Infutor database according to Step 1 of Appendix IA.1. Second, for unmatched inventors, we use the dataset developed by the USPTO Office of the Chief Economist, as reported in Toole, DeGrazia, Myers, Breschi, Ferrucci, Lissoni, Miguelez, Sterzi, and Tarasconi (2019). Toole et al. (2019) develop a process that uses the (primarily first) name of

the inventor and various name–gender dictionaries to attribute the gender of inventors listed on U.S. patents from 1976 to 2016. Third, for the remaining unmatched inventors, we identify their gender using genderize.io and forebears.io, supplemented by manual checks using online sources such as LinkedIn.[75] *Team gender similarity* is then calculated as one minus the Blau (1977) gender diversity measure, where the Blau gender diversity measure = 2 × (1 – [(Percent of team that is female)^2 + (Percent of team that is male)^2]). Higher values of *Team gender similarity* signify less team gender diversity.

To construct *Team age similarity*, we first identify the age of each inventor in the focal team using two sources. First, we use Infutor's Consumer History Plus database, which contains detailed demographic information including the year of birth. Second, for inventors with missing age after utilizing the Infutor database, we use matched inventor age information from the dataset created by Kaltenberg, Jaffe, and Lachman (2023) that is available on Harvard Dataverse. The authors search for age information for U.S. residing inventors from publicly available online web directories, such as Radaris, Spokeo, and Beenverified, based on name and location information from patents. Using these two sources, we obtain age information for 90% of inventors in our sample. For the remaining 10% of inventors with missing age information, we interpolate their age based on other inventors with non-missing age from the same technology class and patenting year. The *Team age similarity* measure is then calculated as –1 multiplied by the standard deviation of age among the R&D team members. This measure is transformed so that its values are bounded between zero and one, where higher values indicate higher age similarity or lower age diversity among team members.

[75] Both genderize.io and forebears.io predict gender based on first names. We fill in gender information for inventors with previously missing values when both genderize.io and forebears.io agree. When they disagree or only one source is available, we manually check using online sources such as LinkedIn and Wikipedia.

Table IA.1: General Social Survey

The table reports results based on individual-level regressions using the U.S. General Social Survey from 1972 to 2016, where the number of observations is the number of respondents for each survey question. THINKSELF asks "If you had to choose, which thing on this list would you pick as the most important for a child to learn to prepare him or her for life?" The answer to this question is reversed so higher values indicate it is more important "to think for himself or herself." OBEYLAW asks "In general, would you say that people should obey the law without exception, or are there exceptional occasions on which people should follow their consciences even if it means breaking the law?" The answer to this question is reversed so higher values indicate people should obey the law without exception rather than follow their consciences. JOBSEC asks "would you please look at this card and tell me which one thing on this list you would most prefer in a job?". The answer to this question is reversed so higher values indicate more importance placed on "no danger being fired". MRMOM/NO GENDEREQ equals one (zero otherwise) if the respondent agrees/strongly agrees with the statement that "it is not good if the man stays at home and cares for the children and the woman goes out to work" or answers "probably should not/definitely should not" to the question that "do you think it should or should not be the government's responsibility to promote equality between men and women?" NO SMOKE equals one (zero otherwise) if the respondent answered no to the question "do you smoke?". NO SELF-CONTROL/WORKHARD equals one (zero otherwise) if the respondent does not think it is important for a child to learn to have self-control or work hard. The main independent variables are the six Hofstede cultural dimensions in the respondent's reported country of ancestry, which are normalized to be between 0 and 1. Ln(Age) is the natural logarithm of the respondent's age at the time of the interview. Male equals one (zero otherwise) if the respondent is male. Ln(Education) is the natural logarithm of the number of years of formal education the respondent has completed. Ln(Income) is the natural logarithm of the respondent's family income converted to 1986 dollars. Married equals one (zero otherwise) if the respondent is married at the time of the interview. White and Black are indicators for the respondent's reported race, where the omitted category is other races. Employed equals one (zero otherwise) if the respondent holds a full-time or a part-time job. Intercepts are included and not reported. Survey year fixed effects are included. Robust standard errors are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Table IA.2: Drivers of co-inventor choice – Subsample of inventors with different countries of origin

This table reports the results of conditional logit models that estimate the factors affecting the choice of co-inventor in the subsample where pairs of inventors are *not* from the same country of origin, using alternative specifications for defining counterfactual control pairs. The dependent variable is equal to one for all new co-inventor pairwise relationships formed at a U.S. publicly listed firm during the sample period and zero for counterfactual pairs that comprise the comparison/control group. Column (1) uses other inventors working at the same firm in the same year as the new actually formed co-inventor pair to form the counterfactual control pairs. Column (2) uses other inventors working at the same firm, in the same year and at the same office to form the counterfactual control pairs. Column (3) uses other inventors working in the same division/subsidiary of a firm at the same time to form the counterfactual control pairs. Column (4) uses other inventors working in the same division/subsidiary of a firm, in the same year and at the same office to form the counterfactual control pairs (see Sections 4.2 and 4.3 for further details). Appendix A provides definitions for all independent variables. All regression specifications include group fixed effects. Robust standard errors (clustered at the group level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Table IA.3: Determinants of choice of co-inventor – More experienced/prolific inventors only

This table reports the results of conditional logit models that estimate the factors affecting the choice of co-inventor. The dependent variable is equal to one for all new co-inventor pairwise relationships formed at a U.S. publicly listed firm during the sample period and zero for counterfactual pairs that comprise the comparison/ control group. Column (1) considers only the collaboration choices of more prolific inventors, defined as inventors whose total number of patents developed to date places them in the top decile (10%) of all inventors in the USPTO universe (i.e., a Top 10% inventor). Column (2) considers only the collaboration choices of inventors with more than 10 years of professional inventor experience up to and including their tenure at their current focal firm. Column (3) considers only the collaboration choices of inventors who have been working at their current focal U.S. public firm for 10 or more years (see Section 6.1 for further details). Appendix A provides definitions for all independent variables. All regression specifications include group fixed effects. Robust standard errors (clustered at the group level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Table IA.4: Innovation output around exogenous co-inventor turnover – Triple diff-in-diff tests (with Firm × Year fixed effects)

This table reports the change in innovative output for treated teams around the death of a co-inventor relative to control teams as defined in equation (3) in Section 5.2.1 (but also with Firm × Year fixed effects). *After*$_{i,t}$ is an indicator variable equal to one for all years after the focal co-inventor's death and zero otherwise. *Treated team*$_i$ is an indicator variable equal to one for all teams that experience the death of a team member and zero otherwise. *Team cultural similarity change*$_i$ is a continuous variable equal to the surviving team's cultural similarity post the focal co-inventor's death minus the pre-death/pre-treatment team's cultural similarity. We measure the quantity of team innovative output each year as *Ln(1+Total patents)*. The average quality of team innovative output is measured as *Ln(1+Average forward citations per patent)*. We measure a team's propensity for producing high impact innovations as *Ln(1+Top 10% cited patents)*. A team is designated as being more (less) focused on exploitative (explorative) innovation if they have higher *Average backward citations per patent* and a higher *Average firm self-cite ratio per patent*. Total net innovation output is measured as *Ln(1+Total citation-weighted patents)*. As outlined in Section 3.3, we include several sets of control variables for the size (and diversity) of a team's knowledge base, the amount (and diversity) of team members' skills, and the amount (and diversity) of experience accumulated by team members, as well as other controls (team geographic diversity). See Appendix A for all variable definitions. All regression specifications include both Team and Firm × Year fixed effects. Robust standard errors (clustered at the team level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Category of innovation outcome	Quantity of innovation	Average quality of innovation	Likelihood of high impact innovation	Relative focus on exploitative innovation		Total net innovation output
Dependent variable	Ln(1+Total patents)	Ln(1+Avg forward cites per patent)	Ln(1+Top 10% cited patents)	Ln(1+Avg back cites per patent)	Avg firm self-cite ratio per patent	Ln(1+Cite weighted patents)

Table IA.5: Heterogeneous treatment effects around co-inventor deaths (treated teams only) with discrete cultural value change measure

This table reports the change in innovative output for treated teams only around the death of a co-inventor (see equation (4) in Section 5.2.4 for further details). *After*$_{i,t}$ is an indicator variable equal to one for all years after the focal co-inventor's death and zero otherwise. *Team cultural similarity increases*$_i$ is a discrete indicator variable that is equal to one for treated teams that experience an increase in their team's cultural value similarity after their co-inventor's premature death, and zero otherwise. We measure the quantity of team innovative output each year as *Ln(1+Total patents)*. The average quality of team innovative output is measured as *Ln(1+Average forward citations per patent)*. We measure a team's propensity for producing high impact innovations as *Ln(1+Top 10% cited patents)*. A team is designated as being more (less) focused on exploitative (explorative) innovation if they have higher *Average backward citations per patent* and a higher *Average firm self-cite ratio per patent*. Total net innovation output is measured as *Ln(1+Total citation-weighted patents)*. As outlined in Section 3.3, we include several sets of control variables for the size (and diversity) of a team's knowledge base, the amount (and diversity) of team members' skills, and the amount (and diversity) of experience accumulated by team members, as well as other controls (team size and team geographic diversity). See Appendix A for definitions of all variables used in this analysis. All regression specifications include Individual dead co-inventor fixed effects, Team fixed effects and Year fixed effects. Robust standard errors (clustered at the team level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Table IA.6: Heterogeneous treatment effects around co-inventor deaths (treated teams only) (inverse hyperbolic sine transformation)

This table reports the change in innovative output for treated teams only around the death of a co-inventor (see equation (4) in Section 5.2.4) but using the inverse hyperbolic sine transformation (*Asinh*) for all patent-related variables rather than the (started) natural log transformation used in Table 6. $After_{i,t}$ is an indicator variable equal to one for all years after the focal co-inventor's death and zero otherwise. *Team cultural similarity change*$_i$ is a continuous variable equal to the surviving team's cultural similarity post the focal co-inventor's death minus the pre-death/pre-treatment team's cultural similarity. We measure the quantity of team innovative output each year as *Asinh(1+Total patents)*. The average quality of team innovative output is measured as *Asinh(Average forward citations per patent)*. We measure a team's propensity for producing high impact innovations as *Asinh(Top 10% cited patents)*. A team is designated as being more (less) focused on exploitative (explorative) innovation if they have a higher average number of backward citations per patent, *Asinh(Average backward citations per patent)*, and a higher *Average firm self-cite ratio per patent*. Total net innovation output is measured as *Asinh(Total citation-weighted patents)*. As outlined in Section 3.3, we include several sets of control variables for the size (and diversity) of a team's knowledge base, the amount (and diversity) of team members' skills, and the amount (and diversity) of experience accumulated by team members, as well as other controls (team geographic diversity). See Appendix A for definitions of all variables used in this analysis. All regressions include Individual dead co-inventor fixed effects, Team fixed effects and Year fixed effects. Robust standard errors (clustered at the team level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.

Table IA.7: Heterogeneous treatment effects around co-inventor deaths (treated teams only) (inclusion of fully interacted controls)

This table reports the change in innovative output for treated teams only around the death of a co-inventor (see equation (4) in Section 5.2.4 for further details). *After*$_{i,t}$ is an indicator variable equal to one for all years after the focal co-inventor's death and zero otherwise. *Team cultural similarity change*$_i$ is a continuous variable equal to the surviving team's cultural similarity post the focal co-inventor's death minus the pre-death/pre-treatment team's cultural similarity. The dependent variables in our analysis are *Ln(1+Total patents)*, *Ln(1+Average forward citations per patent)*, *Ln(1+Top 10% cited patents)*, *Ln(1+Average backward citations per patent)*, *Average firm self-cite ratio per patent*, and *Ln(1+Total citation-weighted patents)*, respectively. As outlined in Section 3.3, we include several sets of control variables for the size (and diversity) of a team's knowledge base, the amount (and diversity) of team members' skills, and the amount (and diversity) of experience accumulated by team members, as well as other controls (team geographic diversity). In this table, we also include as controls the interaction of the post-death change in the average value of each control variable (computed as the post-death period average minus the pre-death period average) with the post-death indicator, *After*$_{i,t}$. See Appendix A for all variable definitions used in this analysis. All regressions include Individual dead co-inventor fixed effects, Team fixed effects and Year fixed effects. Robust standard errors (clustered at the team level) are reported in parentheses. *, ** and *** denote statistical significance at the 10%, 5% and 1% level respectively.
