July 2, 2025

Abstract

We study how distorted beliefs shape stock market risk premia. We propose a novel way to measure the time-varying bias in investors' beliefs and find evidence of both over- and underreaction to information. Decomposing expected returns into belief and bias components reveals that they jointly drive objective market return predictability. Finally, shocks to investor bias manifest themselves as discount-rate risk in the data but are misperceived by investors as cash-flow risk. This creates a wedge between investor pricing and the risk-return relationship observed in the cross-section of expected stock returns, helping to explain the deviations from standard theoretical predictions.

Keywords: distorted beliefs, return predictability, ICAPM, cross-section of stock returns.

1 Introduction

A growing body of evidence suggests that economic agents make predictable forecast errors—i.e., have "distorted beliefs"—about macroeconomic and financial outcomes.[1] Various factors, such as rational inattention or behavioral biases, can distort beliefs, leading agents to either underreact or overreact to relevant information. Recognizing and accounting for these distorted beliefs can provide new insights into empirical asset pricing puzzles that are difficult to explain under the assumption of full-information rational expectations.

In this paper, we investigate the role of distorted beliefs in the stock market, particularly their impact on risk premia. We begin by measuring the conditional bias in investors' beliefs and decompose the predictable component of market returns into two parts: investors' beliefs about future returns and their bias. Variation in this bias manifests itself as discount-rate risk in the data but represents cash-flow risk from investors' perspective. As a result, the bias gives rise to a wedge in observed risk premia, reflecting the difference in the pricing of cash-flow and discount-rate risks. Our findings indicate that distorted beliefs impact both the time series and cross-section of expected returns, helping to explain observed deviations from theoretical predictions, such as those of the Intertemporal Capital Asset Pricing Model (ICAPM).

Our first contribution is to propose a novel way to measure the bias in investors' beliefs—i.e., the difference between beliefs and objective expectations—regarding long-run cash-flow growth and returns. We show that the predictable component of the revisions in investors' cash-flow beliefs identifies the cash-flow bias. In turn, present value identities imply that, in the long-run, cash-flow bias mirrors the bias in expected returns. We estimate this time-varying bias at the market level using revisions in professional analysts' earnings forecasts. By adjusting the statistical expectation of market returns for this bias, we obtain a measure of investors' beliefs about future market returns. The variation in our measure aligns with expectations embedded in index option prices and is consistent with forecasts from industry, banking and government economists, while differing from some other survey-based proxies for expected market returns used in the literature. Overall, our findings suggest that investor beliefs about future market returns are neither constant nor perfectly aligned with the objective variation in expected returns. As a result, it is essential to explicitly allow for the dynamics of these beliefs.

Our second contribution is to show that expectational bias contributes to excess aggregate stock price volatility—i.e., stock price movements unrelated to subsequent movements in

[1] Prominent examples include studies by Coibion and Gorodnichenko (2012, 2015), Greenwood and Shleifer (2014), Adam et al. (2017), Bordalo et al. (2020), Nagel and Xu (2021), Bianchi et al. (2022), and Bordalo et al. (2024a).

cash flows, as hypothesized by Shiller (1981)—but does not explain it completely. Using the decomposition of expected returns into belief and bias components, our analysis reveals that discount-rate beliefs remain a substantial source of stock-market volatility. After accounting for predictability consistent with investor beliefs, we estimate that bias explains approximately 41% of the observed predictability in market returns.

Having estimated the bias in investors' beliefs, our third contribution is to show that this bias can lead to a distorted perception and, consequently, a distorted pricing of risk. A key theoretical insight, originating from Merton (1973) and Campbell (1993), is that financial asset risk premia depend on their return covariances with cash-flow news and expected return—i.e., discount-rate—news. And, non-myopic investors price these two types of risk differently. Under distorted beliefs, investors may misattribute some of the variation in expected returns to the variation in expected cash flows, and vice versa. Specifically, the variation in the bias captures the component of discount-rate risk in the data that investors perceive as cash-flow risk. As a result, even if investors price assets according to the ICAPM, the risk-return relationship predicted by the model will not hold in the data, giving rise to an apparent empirical puzzle.

To gauge the gap between pricing under investor's beliefs and the observed risk-return relationship, we derive a bias-adjusted ICAPM that takes the form of a linear factor model incorporating cash-flow news, discount-rate news, and bias shocks. We compare this model's performance to the traditional Campbell and Vuolteenaho (2004) two-factor bad beta, good beta ICAPM, which excludes bias shocks. Using 51 test portfolios, our findings reveal that incorporating bias shocks significantly enhances the model's pricing performance, with R^2 values increasing from around 3% to around 36%. Despite this improvement, the model still leaves some pricing errors unexplained, particularly for size-sorted portfolios. The bias shock commands a positive and significant risk price in this cross-section, a result further validated using the supervised PCA approach of Giglio et al. (2024), demonstrating the robustness of our results to the asset selection criteria and to additional factors. The results are also robust to using measures of beliefs about stock-level expected returns implied by analysts' price targets. Overall, our findings suggest that accounting for distorted beliefs is crucial for understanding the apparent deviations from the risk-return relationship predicted by the theory.

Finally, our analysis also sheds new light on the sources of distorted beliefs. We note that our estimation approach does not impose a particular belief formation mechanism. Instead, we employ VAR forecasts along with present value restrictions to measure the bias. In particular, this multivariate approach accommodates both overreaction and underreaction to different information. We find evidence consistent with overreaction, as cash flow forecasts tend to negatively predict future forecast revisions and the bias tends to be pro-cyclical. However, we also

observe that investors can have an optimistic bias not only during market booms but also during downturns, suggesting that they may underreact to some information and not adequately revise their expectations downward. Examining the drivers of the estimated bias, we find that biases in stock market and macroeconomic expectations—particularly unemployment expectations—are related. Interestingly, we also find that a more optimistic (pessimistic) bias is associated with lower (higher) risk appetite in the corporate bond market. A potential interpretation of this relationship is that stock market responses lag behind shifts in credit market conditions, resulting in an accumulation of bias. Overall, our evidence is unlikely to be fully accounted for by a simple extrapolative mechanism in which investors overreact uniformly to both positive and negative signals. Instead, our findings better align with theories suggesting asymmetric reactions—specifically, overreaction to good news, as observed during the Dot-com bubble, and underreaction to bad news, as seen during the Global Financial Crisis.

A growing body of literature studies distorted beliefs and their relation to stock market behavior, including studies by Barberis et al. (1998), Bordalo et al. (2019), Nagel and Xu (2021), Bianchi et al. (2024), and Cassella et al. (2024) among others.[2] Closest to our paper are the studies by Chen, Da, and Zhao (2013) and De La O and Myers (2021), which explore excess stock price volatility, and Bordalo et al. (2024a), which investigate market return predictability. The novelty of our work lies in its focus on the pricing of risk. Our findings differ from these authors in other important ways. For instance, contrary to De La O and Myers (2021), our results suggest that discount-rate variation remains an important source of stock-market volatility under investors' beliefs. Motivated by this finding, we extend the analysis of Bordalo et al. (2024a) to incorporate time-varying beliefs about future market returns and disentangle return predictability arising from belief distortions from that consistent with investors' beliefs.

The argument that distorted beliefs can drive variation in expected returns has been advanced by Kozak et al. (2018). The authors propose a model in which sentiment-driven investors induce fluctuations in expected returns, which creates an inter-temporal risk for rational investors.[3] Our work builds on a related yet distinct premise: a representative non-myopic investor with distorted beliefs mistakes some of the variation in expected returns (expected cash flow) for variation in expected cash-flow (expected returns), and mis-prices this component of risk. We take this framework to the data and find empirical support for its predictions.

Our work is also related to the literature on the distorted beliefs about the macroeconomy; see Coibion and Gorodnichenko (2015), Bordalo et al. (2020), Bianchi et al. (2022), Bhandari

[2]While the literature, including our paper, has primarily focused on distorted beliefs at the market level, recent studies have also examined beliefs regarding firm-level earnings; see Bordalo et al. (2024b).

[3]See Section IV in Kozak et al. (2018).

et al. (2024), among others. In particular, we find a significant relationship between agents' biases in market cash flow (and market return) expectations and biases in unemployment expectations. This finding further aligns with contemporaneous work by De la O et al. (2025), who construct a factor summarizing the difference between subjective and statistical expectations across 24 macroeconomic variables, and show that this factor is associated with several anomalies in the cross-section of stock returns. By contrast, we show that the bias in investor beliefs about market cash flow and discount rate risks are related to—though not entirely explained by—macroeconomic expectations. More broadly, we refer readers to the comprehensive overview by Bachmann et al. (2023) for a detailed survey of the growing literature on subjective macroeconomic expectations.

Belief distortions are implicit in the market timing theory of capital structure as proposed by Baker and Wurgler (2002). We find a positive albeit moderate correlation between the stock market sentiment index proposed by Baker and Wurgler (2006) that builds on this capital structure theory and our measure of the bias in investors' beliefs. Overall, our findings indicate that our measure effectively captures both previously studied dimensions of belief distortions as well as additional dimensions not identified in prior research.

Our paper is also related to an emerging empirical literature examining return expectations among major institutional investors. Dahlquist and Ibert (2024) document large asset managers' equity premium expectations are countercyclical and closely aligned with their portfolio allocations. Couts, Goncalves, and Loudis (2025) and Couts, Goncalves, Liu, and Loudis (2025) analyze the risk and return expectations of leading asset managers and institutional investment consultants, as reflected in their long-term capital market assumptions. They find that the majority of variation in subjective return expectations arises from differences in perceived risk premia, rather than differences in perceived alpha. Taken together, these findings align with our premise that a meaningful subjective riskreturn tradeoff is embedded in investor beliefs and reflected in both investment behavior and asset prices.

Finally, our analysis builds on the present value framework developed by Campbell and Shiller (1988), Campbell (1991), Campbell (1993), and applied by Campbell and Vuolteenaho (2004) and Campbell et al. (2013), among others. Recent work has extended this framework in several directions. For instance, Campbell et al. (2018) incorporate stochastic volatility, while Gao and Martin (2021) consider higher-order approximation terms and use options data. In our paper, we explore a different extension of this framework and examine the implications of present value relationships under distorted beliefs.

The rest of the paper is organized as follows. Section 2 presents our analytical framework. Section 3 describes our data. Section 4 presents our main empirical results. Section 5 con-

cludes. An Internet Appendix contains proofs and additional empirical results.

2 Analytical Framework

2.1 Objective beliefs benchmark

To analyze the impact of distorted beliefs on the standard predictions of asset pricing theory, we consider the Campbell (1993) version of the ICAPM derived in the Campbell and Shiller (1988) and Campbell (1991) homoscedastic log-linear present value framework. For analytical tractability, we further assume log-normality. To establish our notation, we provide a brief overview of this standard framework and refer to the original papers for a more detailed discussion of the underlying assumptions.

The market log return r_t can be approximated as

$$r_{t+1} \approx k + \Delta d_{t+1} + \rho \left(p_{t+1} - d_{t+1} \right) - \left(p_t - d_t \right), \tag{1}$$

where Δd_t is the market dividend growth, $p_t - d_t$ is the market log price-to-dividend ratio, and k and ρ are constants. Iterating equation (1) forward, assuming $\lim_{h \to \infty} \rho^h \mathbb{E}_t (p_{t+h} - d_{t+h}) = 0$, and taking expectations, the market valuation depends on the difference between expected cash-flow growth $\mathcal{F}_{d,t}$ and expected discount rates $\mathcal{F}_{r,t}$

$$p_t - d_t \approx \frac{k}{1-\rho} + \underbrace{\mathbb{E}_t \sum_{h=0}^{\infty} \rho^h \Delta d_{t+1+h}}_{\equiv \mathcal{F}_{d,t}} - \underbrace{\mathbb{E}_t \sum_{h=0}^{\infty} \rho^h r_{t+1+h}}_{\equiv \mathcal{F}_{r,t}}, \tag{2}$$

Combining equations (1) and (2), we obtain the decomposition of aggregate market return innovations $r_{t+1} - \mathbb{E}_t r_{t+1}$ into cash-flow news $\varepsilon_{d,t+1}$ and discount-rate news $\varepsilon_{r,t+1}$

$$r_{t+1} - \mathbb{E}_t r_{t+1} \approx \underbrace{\left(\mathbb{E}_{t+1} - \mathbb{E}_t \right) \sum_{h=0}^{\infty} \rho^h \Delta d_{t+1+h}}_{\equiv \varepsilon_{d,t+1}} - \underbrace{\left(\mathbb{E}_{t+1} - \mathbb{E}_t \right) \sum_{h=1}^{\infty} \rho^h r_{t+1+h}}_{\equiv \varepsilon_{r,t+1}}. \tag{3}$$

Under Campbell (1993) ICAPM, for any asset return $r_{i,t}$ and corresponding excess return $r^e_{i,t}$

$$\mathbb{E}_t r^e_{i,t+1} + \frac{\mathbb{V}\text{ar}_t r_{i,t+1}}{2} \approx \gamma \times \mathbb{C}\text{ov}_t \left[r_{i,t+1}, \varepsilon_{d,t+1} \right] - 1 \times \mathbb{C}\text{ov}_t \left[r_{i,t+1}, \varepsilon_{r,t+1} \right], \tag{4}$$

where γ is the representative investor's coefficient of relative risk aversion.

2.2 Distorted beliefs

We now assume that, in the framework described above, the representative investor uses an equivalent probability measure $\mathbb{S}$ that differs from the objective probability measure $\mathbb{P}$. For instance, investor might hold diagnostic expectations as in Bordalo et al. (2024a). However, our framework is intentionally general and we remain agnostic about the belief formation mechanism that gives rise to $\mathbb{S}$.

That said, we assume that investor's beliefs are internally consistent and constrained by the present value relationships: beliefs about cash-flow growth and expected returns may differ from their objective expectations, but these two components have to add up to prevailing market valuations. In other words, from investor's perspective, the present value identity (2) holds but with expectations taken under $\mathbb{S}$.[4,5]

The discrepancy between $\mathbb{S}$ and $\mathbb{P}$ introduces a bias in investor's beliefs. Our primary focus is on the conditional bias—the difference between conditional expectations under $\mathbb{S}$ and $\mathbb{P}$—and the impact that its time-variation has on asset price fluctuations.[6] Comparing equation (2) with expectations taken, respectively, under $\mathbb{S}$ and under $\mathbb{P}$ we note that, the bias in long-run cash-flow expectations corresponds to an equal bias in long-run market return expectations, and vice versa. Indeed, since both investors and statistical beliefs are consistent with observed $p_t - d_t$, we have:

$$\mathbb{E}_t^{\mathbb{S}} \sum_{h=0}^{\infty} \rho^h \left(\Delta d_{t+1+h} - r_{t+1+h}\right) = \mathbb{E}_t^{\mathbb{P}} \sum_{h=0}^{\infty} \rho^h \left(\Delta d_{t+1+h} - r_{t+1+h}\right),$$

which after rearranging gives

$$\underbrace{(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}}) \sum_{h=0}^{\infty} \rho^h \Delta d_{t+1+h}}_{=\mathcal{F}_{d,t}^{\mathbb{S}} - \mathcal{F}_{d,t}^{\mathbb{P}} \equiv \mathcal{B}_t^{\mathbb{S}-\mathbb{P}}} = \underbrace{(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}}) \sum_{h=0}^{\infty} \rho^h r_{t+1+h}}_{\mathcal{F}_{r,t}^{\mathbb{S}} - \mathcal{F}_{r,t}^{\mathbb{P}}}. \tag{5}$$

[4]This relies on two technical conditions. First, we assume that $\lim_{h\to\infty} \rho^h \mathbb{E}_t^{\mathbb{S}}(p_{t+h} - d_{t+h}) = 0$, ruling out bubbles under distorted beliefs. Second, we assume that the linearization parameter ρ is the same under both $\mathbb{P}$ and $\mathbb{S}$. This can be viewed as a simplifying approximation as in Nagel (2024). Alternatively, it can be justified by assuming that the investor knows the objective long-run mean of the log price-to-dividend ratio, which determines ρ, even though her conditional beliefs may deviate from objective expectations, as in Bordalo et al. (2024a).

[5]Brown et al. (2016), Huang et al. (2023), and Bastianello et al. (2025), among others, document that a large fraction of analysts directly rely on the discounted cash flow framework to form their forecasts and make investment recommendations. Additionally, many analysts consider the price-to-earnings ratio multiple, which can be seen as a simplified, reduced-form version of the discounted cash flow approach.

[6]We allow for but do not emphasize a potential unconditional bias, to the extent that it is not driving asset price fluctuations. In fact, we do not require that the bias converges in the limit. Later in this section, we impose a no-bubble-type condition on the speed at which beliefs can diverge from objective expectations.

For example, consider overly optimistic beliefs about future cash-flow growth. These beliefs inflate market valuations, resulting in lower long-run returns relative to investor's expectations.[7]

We will refer to the term $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ in equation (5), which captures the discrepancy between investor's belief and objective expectation of both aggregate cash flows and market returns, as simply the *bias*. A higher (lower) value of $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ indicates that the investor holds more optimistic (pessimistic) beliefs compared to the objective forecast. For convenience, we also refer to the negation $\mathcal{B}_t^{\mathbb{P}-\mathbb{S}} = -\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ as bias. Multiplying equation (5) evaluated at $t+1$ by ρ and subtracting the same equation evaluated at t, we obtain a relationship between the bias in cash-flow and discount-rate news defined in equation (3)

$$\underbrace{\varepsilon_{d,t+1}^{\mathbb{S}} - \varepsilon_{d,t+1}^{\mathbb{P}}}_{\rho\mathcal{B}_{t+1}^{\mathbb{S}-\mathbb{P}} - \mathcal{B}_t^{\mathbb{S}-\mathbb{P}}} = \varepsilon_{r,t+1}^{\mathbb{S}} - \varepsilon_{r,t+1}^{\mathbb{P}} - \underbrace{(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}})r_{t+1}}_{\text{time-}t\text{ term}}. \tag{6}$$

Importantly, the bias $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ can be inferred from the way the investor revises her beliefs. Taking conditional expectations under $\mathbb{P}$ of the definition on the left-hand side of equation (6), $\rho\mathcal{B}_{t+1}^{\mathbb{S}-\mathbb{P}} - \mathcal{B}_t^{\mathbb{S}-\mathbb{P}} = \varepsilon_{d,t+1}^{\mathbb{S}} - \varepsilon_{d,t+1}^{\mathbb{P}}$, we have

$$\rho\mathbb{E}_t^{\mathbb{P}}\mathcal{B}_{t+1}^{\mathbb{S}-\mathbb{P}} - \mathcal{B}_t^{\mathbb{S}-\mathbb{P}} = \mathbb{E}_t^{\mathbb{P}}\varepsilon_{d,t+1}^{\mathbb{S}} - \underbrace{\mathbb{E}_t^{\mathbb{P}}\varepsilon_{d,t+1}^{\mathbb{P}}}_{=0}.$$

By iterating forward and imposing a condition, $\lim_{h\to\infty}\rho^h\mathbb{E}_t^{\mathbb{P}}\mathcal{B}_{t+h}^{\mathbb{S}-\mathbb{P}} = 0$, which allows beliefs to deviate from objective expectations in the limit while ensuring that such divergences do not become explosive, we obtain

$$\mathcal{B}_t^{\mathbb{S}-\mathbb{P}} = -\sum_{h=0}^{\infty}\rho^h\mathbb{E}_t^{\mathbb{P}}\varepsilon_{d,t+1+h}^{\mathbb{S}}. \tag{7}$$

From equation (7), the bias equals the predictable component of future revisions in investor's beliefs. Rather than directly measuring the difference between conditional expectations under $\mathbb{S}$ and under $\mathbb{P}$, this approach exploits the failure of the Law of Iterated Expectations which arises when $\mathbb{S} \neq \mathbb{P}$. In our empirical implementation, expectations under $\mathbb{P}$ are proxied by statistical expectations conditional on a set of state variables. Equation (7) measures the bias as an expectation conditional on the same information set. This ensures that our bias measure

[7]This holds true even if investor is not marginal: low market valuations that do not reflect her optimism about future cash-flow growth imply, from investor's perspective, high expected returns, which ultimately fail to materialize.

does not simply reflect information available to the investor but not to the econometrician, and instead captures the distortion in investor beliefs given the same information.[8]

2.3 Bias in the expected market return

Investor bias accounts for part of the objective predictability in market returns. Appendix A.1 shows the decomposition of the H-period expected weighted return into investor's belief and the effect of distorted beliefs. As $H \to \infty$, this decomposition reduces to equation (5), with the effect of distorted beliefs converging to $\mathcal{B}_t^{\mathbb{P}-\mathbb{S}}$, itself given by equation (7):

$$\underbrace{\mathbb{E}_t^{\mathbb{P}} \sum_{h=0}^{\infty} \rho^h r_{t+1+h}}_{\text{objective, } \mathcal{F}_{r,t}^{\mathbb{P}}} = \underbrace{\mathbb{E}_t^{\mathbb{S}} \sum_{h=0}^{\infty} \rho^h r_{t+1+h}}_{\text{belief, } \mathcal{F}_{r,t}^{\mathbb{S}}} + \underbrace{\mathbb{E}_t^{\mathbb{P}} \sum_{h=0}^{\infty} \rho^h \varepsilon_{d,t+1+h}^{\mathbb{S}}}_{\text{belief distortion, } \mathcal{B}_t^{\mathbb{P}-\mathbb{S}}}. \tag{8}$$

2.4 Bias in the cross-section of expected returns

The bias can also shape expected returns observed in the cross-section. We start from an intuitive benchmark suggested by finance theory and assume that, from investor's perspective, excess returns compensate for assets' exposure to cash-flow and discount-rate risks. More formally, we assume that the ICAPM in equation (4) holds under $\mathbb{S}$.

The discrepancy between $\mathbb{S}$ and $\mathbb{P}$ creates a wedge between the risk-return relationship that holds under investor's beliefs and the relationship observed in the data. To characterize the risk-return relationship under $\mathbb{P}$, we express expected returns similarly to Adam and Nagel (2023) and Jensen (2024) as the sum of a stock-level bias and the required compensation for perceived risk:

$$\mathbb{E}_t^{\mathbb{P}} r_{i,t+1}^e + \frac{\mathbb{V}\text{ar}_t^{\mathbb{S}} r_{i,t+1}}{2} \approx -\left(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}}\right) r_{i,t+1}^e + \mathbb{C}\text{ov}_t^{\mathbb{S}}\left[r_{i,t+1}, \gamma \varepsilon_{d,t+1}^{\mathbb{S}} - \varepsilon_{r,t+1}^{\mathbb{S}}\right]. \tag{9}$$

Focusing first on the covariance term in Equation (9), the investor misjudges risk, evaluating asset return covariance with cash-flow news $\varepsilon_{d,t}^{\mathbb{S}}$ and discount-rate news $\varepsilon_{r,t}^{\mathbb{S}}$ rather than their objective counterparts. Using equation (6), we can quantify the resulting difference as

$$\gamma \varepsilon_{d,t+1}^{\mathbb{S}} - \varepsilon_{r,t+1}^{\mathbb{S}} = \gamma \varepsilon_{d,t+1}^{\mathbb{P}} - \varepsilon_{r,t+1}^{\mathbb{P}} + (\gamma - 1) \underbrace{\left(\varepsilon_{d,t+1}^{\mathbb{S}} - \varepsilon_{d,t+1}^{\mathbb{P}}\right)}_{\rho \mathcal{B}_{t+1}^{\mathbb{S}-\mathbb{P}} - \mathcal{B}_t^{\mathbb{S}-\mathbb{P}}} - \underbrace{\left(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}}\right) r_{t+1}}_{\text{time-}t\text{ term}}. \tag{10}$$

[8] In our empirical implementation, we use a parsimonious set of publicly observed state variables, making it also unlikely that the econometrician has an informational advantage over the investor.

The term in $\rho\mathcal{B}_{t+1}^{\mathbb{S}-\mathbb{P}} - \mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ in equation (10) arises because shocks to the bias manifest themselves as discount-rate risk in the data but represent cash-flow risk from investor's perspective. Since cash-flow and discount-rate risks are priced differently when $\gamma \neq 1$, this distinction affects expected returns. Note that this term does not introduce an additional risk factor—i.e., the investor does not price the risk of her own bias—but instead measures the wedge between perceived and objective risk ($\gamma\varepsilon_{d,t+1}^{\mathbb{S}} - \varepsilon_{r,t+1}^{\mathbb{S}}$ and $\gamma\varepsilon_{d,t+1}^{\mathbb{P}} - \varepsilon_{r,t+1}^{\mathbb{P}}$, respectively).

Next, note that the second-moment operators, $\mathbb{V}\text{ar}_t$ and $\mathbb{C}\text{ov}_t$, in equation (9) remain approximately invariant under the change of measure. This result is intuitively related to Girsanov's theorem, which preserves the volatility of a stochastic process under a measure change. In our discrete-time log-normal setting this property holds approximately, as shown in Appendix A.1.[9]

Finally, the asset-specific bias $\left(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}}\right) r_{i,t+1}^e$ in equation (9) simplifies considerably in two plausible cases. First, this bias will tend to average out in cross-sectional asset pricing tests $\mathbb{E}^{\mathbb{P}}\left(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}}\right) r_{i,t+1}^e = 0$, unless investors are unconditionally either overly optimistic or overly pessimistic about asset-i returns. Second, if asset-specific bias stems from distorted beliefs about aggregate risk factors, it will be proportional to the return covariance with these factors. For instance, consider an investor with distorted beliefs about aggregate cash flow: $\frac{d\mathbb{S}}{d\mathbb{P}} = S_t$ with $\frac{S_{t+1}}{S_t} \approx 1 + s_t\varepsilon_{d,t+1}^{\mathbb{P}}$, where the process s_t determines the distortion of cash-flow news $\varepsilon_{d,t+1}^{\mathbb{P}}$.[10] Under this assumption, we have

$$(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}})r_{i,t+1} \approx s_t \times \mathbb{C}\text{ov}_t\left[r_{i,t+1}, \varepsilon_{d,t+1}^{\mathbb{P}}\right] \text{ and } \mathcal{B}_t^{\mathbb{S}-\mathbb{P}} \approx s_t \times \mathbb{V}\text{ar}_t\left[\varepsilon_{d,t+1}^{\mathbb{P}}\right].$$

Combining together, we obtain

$$(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}})r_{i,t+1} \approx \frac{\mathbb{C}\text{ov}_t\left[r_{i,t+1}, \varepsilon_{d,t+1}^{\mathbb{P}}\right]}{\mathbb{V}\text{ar}_t\left[\varepsilon_{d,t+1}^{\mathbb{P}}\right]} \times \mathcal{B}_t^{\mathbb{S}-\mathbb{P}}.$$

In either of these two cases, the unconditional version of the risk-return relationship (9)

[9] This property does not imply that investors assess risk correctly, as evident from equation (10). Rather, in our setting, the change of measure does not introduce bias into the second moments of a given shock. Extending our framework to a stochastic volatility environment, where investors hold biased beliefs about volatility, represents a promising avenue for future research. Lochstoer and Muir (2022) take a first step in this direction, showing that investor beliefs about stock market volatility exhibit sluggish underreaction to volatility shocks, followed by delayed overreaction.

[10] This expression provides a discrete-time approximation of a stochastic exponential. Here and in what follows we assume that continuous-time results hold approximately in our discrete-time setting.

simplifies to

$$\mathbb{E}^{\mathbb{P}} R^e_{i,t} \approx \lambda_d \mathbb{C}\text{ov}^{\mathbb{P}}\left[r_{i,t}, \varepsilon^{\mathbb{P}}_{d,t}\right] + \lambda_r \mathbb{C}\text{ov}^{\mathbb{P}}\left[r_{i,t}, \varepsilon^{\mathbb{P}}_{r,t}\right] + \lambda_{\mathcal{B}} \mathbb{C}\text{ov}^{\mathbb{P}}\left[r_{i,t}, \varepsilon_{\mathcal{B},t}\right], \tag{11}$$

where $R^e_{i,t}$ is the simple excess return on asset i, $\varepsilon_{\mathcal{B},t+1}$—the bias shock—represents the innovation component of $\rho\mathcal{B}^{\mathbb{S}-\mathbb{P}}_{t+1} - \mathcal{B}^{\mathbb{S}-\mathbb{P}}_t$, and $\lambda_d, \lambda_r, \lambda_{\mathcal{B}}$ are factor loadings.[11] We will use equation (11) to test the effect of distorted beliefs on the cross-section of stock returns.

Investors may also display a purely idiosyncratic cross-sectional pattern in their unconditional optimism or pessimism about individual stocks. In this case, the asset-specific bias, $\mathbb{E}^{\mathbb{P}}\left(\mathbb{E}^{\mathbb{S}}_t - \mathbb{E}^{\mathbb{P}}_t\right) r^e_{i,t+1}$, introduces an additional noise component in equation (11). Consequently, empirical tests of equation (11) provide a lower bound on the role of belief distortions. Correcting for this noise term requires data on investor beliefs about individual stock returns, an exercise that we consider in our empirical analysis.

2.5 VAR identification

Finally, to measure the key terms in equations (8) and (11), we consider the VAR model

$$\mathbf{x}_{t+1} = \mathbf{B}\mathbf{x}_t + \mathbf{u}_{t+1} \tag{12}$$

where $\mathbf{x}_t = (r^e_t \, \varepsilon^{\mathbb{S}}_{d,t} \, \mathbf{z}_t)^\intercal$ is a vector that includes excess market returns r^e_t, revisions in investor's forecasts of cash-flow growth $\varepsilon^{\mathbb{S}}_{d,t}$, and a set of predictive variables $\mathbf{z}_t$. As discussed in the next section, the forecast revisions $\varepsilon^{\mathbb{S}}_{d,t}$ can be constructed from analysts' earnings forecasts. All variables are demeaned to simplify notation.

The VAR model (12) serves a dual purpose of uncovering statistical predictability in both market returns and forecast revisions, ensuring that both forecasts are conditional on the same information set. First, we follow Campbell and Vuolteenaho (2004) and exploit market return predictability captured by the VAR model to obtain discount-rate news

$$\varepsilon^{\mathbb{P}}_{r,t+1} = \mathbf{e}_1^\intercal \rho \mathbf{B} \left(\mathbf{I} - \rho \mathbf{B}\right)^{-1} \mathbf{u}_{t+1}, \tag{13}$$

where $\mathbf{e}_1 = (1\ 0\ 0 ... 0)^\intercal$ is a selection vector. From equation (3), discount-rate and cash-flow news add up to the innovation in market returns, implying $\varepsilon^{\mathbb{P}}_{d,t+1} = \varepsilon^{\mathbb{P}}_{r,t+1} + \mathbf{e}_1^\intercal \mathbf{u}_{t+1}$.

Next, from equation (7), the bias is equal to the predictable component of forecast revisions

[11] For instance, in the case above, the loadings are $\lambda_d = \gamma - \frac{\mathbb{E}\mathcal{B}^{\mathbb{S}-\mathbb{P}}_t}{\mathbb{V}\text{ar}\varepsilon^{\mathbb{P}}_{d,t+1}}$, $\lambda_r = -1$, $\lambda_{\mathcal{B}} = \gamma - 1$. If, in additon, the investor is not unconditionally biased, we have $\mathbb{E}\left[\mathcal{B}^{\mathbb{S}-\mathbb{P}}_t\right] = 0$ and the asset-specific bias term vanishes altogether.

and therefore we have

$$\mathcal{B}_t^{\mathbb{S}-\mathbb{P}} = -\mathbf{e}_2^{\intercal}\mathbf{B}(\mathbf{I} - \rho\mathbf{B})^{-1}\mathbf{x_t}, \tag{14}$$

where $\mathbf{e}_2 = (0\ 1\ 0...0)^{\intercal}$ is a selection vector. Additionally, for convenience, we will refer to the the innovation component of forecast revisions $\varepsilon_{d,t+1}^{\mathbb{S}}$ as the belief shock equal to $\mathbf{e}_2^{\intercal}\mathbf{u}_{t+1}$, and to the innovation component of $\rho\mathcal{B}_{t+1}^{\mathbb{S}-\mathbb{P}} - \mathcal{B}_t^{\mathbb{S}-\mathbb{P}} = \varepsilon_{d,t+1}^{\mathbb{S}} - \varepsilon_{d,t+1}^{\mathbb{P}}$ as the bias shock denoted by $\varepsilon_{\mathcal{B},t+1}$ and equal to

$$\varepsilon_{\mathcal{B},t+1} = \mathbf{e}_2^{\intercal}\mathbf{u}_{t+1} - \varepsilon_{d,t+1}^{\mathbb{P}}. \tag{15}$$

Finally, we note an alternative way to identify cash-flow and discount-rate news in the VAR model (12). From equation (6) we can obtain cash-flow news as

$$\varepsilon_{d,t+1}^{\mathbb{P}} = \varepsilon_{d,t+1}^{\mathbb{S}} - \rho\mathcal{B}_{t+1}^{\mathbb{S}-\mathbb{P}} + \mathcal{B}_t^{\mathbb{S}-\mathbb{P}}, \tag{16}$$

which, through relationship (3), implies that discount-rate news are equal to $\varepsilon_{r,t+1}^{\mathbb{P}} = \varepsilon_{d,t+1}^{\mathbb{P}} - \mathbf{e}_1^{\intercal}\mathbf{u}_{t+1}$. Intuitively, equation (16) shows that (changes in) objective cash-flow growth forecast can be recovered from investor's beliefs corrected for their bias. Comparing the shocks identified through the Campbell and Vuolteenaho (2004) approach with those identified using this alternative approach can serve as a consistency test for our framework.

3 Data

3.1 Earnings forecasts

To construct empirical proxies at the monthly frequency for investors' forecast of market earnings growth ($\mathcal{F}_{d,t}^{\mathbb{S}}$) and for the revisions in this forecast ($\varepsilon_{d,t}^{\mathbb{S}}$), we use the analysts' median forecast of earnings per share and long-run earnings growth from the Thomson Reuters I/B/E/S Estimates Database available from January 1982 onwards. The I/B/E/S data have been extensively used in the literature on distorted beliefs. In particular, De La O and Myers (2021) use short-term earnings per share forecasts whereas Bordalo et al. (2024a) examine long-term growth forecasts. In our analysis, we incorporate both short- and long-term forecasts, as explained below.

As a first step, we obtain market-level forecast by aggregating the earnings per share forecast at one- and two-year horizons as well the long-term growth forecast across all S&P 500 stocks. In a second step, we consider two alternative ways to aggregate forecasts at different horizons to obtain a measure of $\mathcal{F}_{d,t}^{\mathbb{S}} = \mathbb{E}_t^{\mathbb{S}} \sum_{h=0}^{\infty} \rho^h \Delta d_{t+1+h}$. In each approach, we assume a

constant payout ratio, implying that dividend growth equals earnings growth.

Appendix Figure A-1 illustrates the coverage of firm-level earnings forecasts for S&P 500 constituents. While coverage is high for 1- and 2-year-ahead forecasts as well as for long-term growth (LTG), it declines sharply for horizons of 3, 4, and 5 years. For this reason, in our baseline approach, we follow Bordalo et al. (2024) and measure $\mathcal{F}^{\mathbb{S}}_{d,t}$ by combining the one- and two-year expected growth rates implied by earnings per share forecasts at the one-year (EPS^{1y}_t) and two-year (EPS^{2y}_t) horizons.[12] We also assume that the growth rate between years two and ten equals the long-term growth forecast (LTG), and that the growth rate g^∞ beyond the analysts' long-term forecast horizon, which we set at ten years, is constant:

$$\mathcal{F}^{\mathbb{S}}_{d,t} = \ln \frac{EPS^{1y}_t}{EPS_t} + \rho_a \ln \frac{EPS^{2y}_t}{EPS^{1y}_t} + \frac{\rho_a^2(1-\rho_a^8)}{1-\rho_a} LTG_t + \frac{\rho_a^{10}}{1-\rho_a} g^\infty, \tag{17}$$

where $\rho_a = \rho^{12}$.[13] Further, we calibrate g^∞ such that the unconditional mean of $\mathcal{F}^{\mathbb{S}}_{d,t}$ matches the unconditional mean of the price-to-earnings ratio.[14] Since g^∞ does not contribute to the variation in $\mathcal{F}^{\mathbb{S}}_{d,t}$, it plays a minimal role in our analysis: while it determines the unconditional mean of the bias, it does not influence its time-varying component, which is the primary focus of our study. As can be seen from equation (17), our baseline approach considers the information contained in both short-term as well as long-term analyst forecasts.

As an alternative, we follow De La O and Myers (2021) and posit a "decay" model for cash-flow expectations:

$$\mathbb{E}^{\mathbb{S}}_t \Delta d_{t+1+h} - g^\infty = \phi^h \left(\mathbb{E}^{\mathbb{S}}_t \Delta d_{t+1} - g^\infty \right),$$

where the decay parameter ϕ (= 0.445) is estimated by regressing the two-year expected growth rate implied by earnings per share forecasts on the one-year expected growth rate. We then measure $\mathcal{F}^{\mathbb{S}}_{d,t}$ as

$$\mathcal{F}^{\mathbb{S}}_{d,t} = \frac{1}{1-\rho_a\phi} \ln \frac{EPS^{1y}_t}{EPS_t} + \left(\frac{1}{1-\rho_a} - \frac{1}{1-\rho_a\phi} \right) g^\infty. \tag{18}$$

[12] Similarly, Chen et al. (2013) compute implied cost of capital employing earnings forecasts 1- and 2-years ahead (i.e., for the current and next fiscal year), and the long-term growth forecast.

[13] Following Bordalo et al. (2024), we calibrate $\rho_a = (1+e^{-pd})^{-1} \approx 0.9777$ where pd equals the unconditional sample mean of the log price-to-dividend ratio.

[14] That is, g is the average of the growth rate g_t obtained by solving, at each time t, the equation $pe_t = \frac{\kappa - r}{1-\rho_a} + \rho_a \ln \frac{EPS^{2y}_t}{EPS^{1y}_t} + \frac{\rho_a^2(1-\rho_a^8)}{1-\rho_a} LTG_t + \frac{\rho_a^{10}}{1-\rho_a} g_t$, where κ is defined as in Bordalo et al. (2024) and r equals the unconditional mean return in our sample.

As can be seen from equation (18), this second approach relies only on information contained in short-term analyst forecasts. As above, we calibrate g^{∞} such that the unconditional mean of $\mathcal{F}^{\mathbb{S}}_{d,t}$ matches the unconditional mean of the price-to-earnings ratio.

Finally, for each measure of $\mathcal{F}^{\mathbb{S}}_{d,t}$ we calculate cash-flow forecast revisions $\varepsilon^{\mathbb{S}}_{d,t+1} = (\mathbb{E}^{\mathbb{S}}_{t+1} - \mathbb{E}^{\mathbb{S}}_{t}) \sum_{h=0}^{\infty} \rho^h \Delta d_{t+1+h}$ as

$$\varepsilon^{\mathbb{S}}_{d,t} = \frac{\ln EPS_t - \ln EPS_{t-12}}{12} + \rho \mathcal{F}^{\mathbb{S}}_{d,t} - \mathcal{F}^{\mathbb{S}}_{d,t-1},$$

where we approximate the growth in realised monthly earnings per share with the average monthly growth rate over the last year. Note that simply calculating monthly first differences in $\mathcal{F}^{\mathbb{S}}_{d,t}$ would yield series that are highly correlated with the revisions $\varepsilon^{\mathbb{S}}_{d,t}$, with correlation coefficient equal to 0.96.

To construct investors' forecast of market earnings growth ($\mathcal{F}^{\mathbb{S}}_{d,t}$) and the associated cash-flow forecast revisions $\varepsilon^{\mathbb{S}}_{d,t+1}$ at the monthly frequency, we need to interpolate realized quarterly earnings from Compustat as well as earning per share forecasts at different horizons from Thomson Reuters I/B/E/S. From quarterly balance sheet data, we first compute the year-over-year cumulative earnings for each quarter t. Second, we perform a linear interpolation of cumulative earnings from two adjacent quarters to construct monthly realised cumulative earnings and earnings per share, respectively.[15] Further, we construct monthly analyst forecasts of earnings using the methodology on horizon interpolation outlined in the Appendix B of De La O and Myers (2021).

One might be concerned that analysts' earnings forecasts are distorted due to agency conflicts. However, Bordalo et al. (2019, 2024a) argue that such conflicts are unlikely to affect the time-series variation of forecasts, which is the focus of our analysis. Moreover, brokerage houses typically cover all S&P 500 firms. Therefore, investment banking relationships and analyst sentiment which could incentivize analysts to cover specific firms are not a concern in our sample. In addition, it is important to note that Thomson Reuters gathers their forecasts from hundreds of brokerage houses and independent analysts who track companies as part of their investment research work. Each individual estimate is identified by the name of the analyst or brokerage firm. Because the forecasts are not anonymous, analysts have a strong incentive to accurately report their expectations. In line with this conjecture, previous literature finds evidence that accuracy in earnings forecasts is important for tenure and compensation of analysts; see Mikhail et al. (1999) and Cooper et al. (2001). Furthermore, it has been shown that financial firms' behaviour correlates significantly with their own analysts' forecasts further substantiat-

[15] For more details on the measurement of earnings consistent with I/B/E/S's definition of earnings see A.2

ing the validity of the forecasts. For example, Bradshaw (2004) shows that individual earnings forecasts are correlated with Buy/Sell recommendations, while Chan et al. (2009) show that financial firms' own stock holding changes are significantly positively related to recommendation changes.

Another possible concern regarding the analysts forecasts is that respondents may be using risk-neutral probabilities in forming their expectations. This would imply that analysts overweight negative outcomes and, as a result, consistently under-predict future cash flows. However, that is not what we observe in the data. In fact, analysts forecast errors have zero or negative means, implying a slightly optimistic average bias, the opposite of what we would expect if analysts would indeed be applying risk-neutral probabilities.

3.2 Other data

VAR variables. We use returns of the S&P 500 index in excess of Treasury Bills as a proxy for excess returns on the market (r_t^e). Our market index choice is motivated by the coverage of analysts' earnings forecasts, as discussed above. To be consistent, we construct the price-to-dividend ratio (pd_t) for the S&P 500 by taking the difference between the logarithm of the price and the logarithm of the twelve-months smoothed dividends paid on S&P 500 stocks; see also Goyal and Welch (2008).

Following Campbell and Vuolteenaho (2004), the yield spread (ty_t) is defined as the difference between the long-term yield on government bonds and the short-term taxable Treasury bill yield; the small-stock value spread (vs_t) is measured as the difference between the log book-to-market ratios of small value and small growth stocks; and the default spread (def_t) is defined as the difference between the log yield on Moody's BAA and AAA bonds which are obtained from Amit Goyal's website.

Portfolios. For our cross-sectional asset pricing tests, we use various standard portfolios as test assets. That is, we first rely on a cross-section which consists out of the following 51 test assets: 30 portfolios sorted by market capitalization (ME), book-to-market ratio (BE/ME), and past returns, available from Professor Kenneth French's website; 20 portfolios sorted on past risk loadings as measured by our VAR state variables (following Campbell and Vuolteenaho (2004)); and the return on the S&P 500. Second, we rely on the data from Chen and Zimmermann (2022) which includes a large number of equity portfolios sorted by characteristics.

Survey data. The Livingstone survey is conducted by the Federal Reserve Bank of Philadelphia and have been used by Adam et al. (2021) and Dahlquist and Ibert (2024), among others. We obtain the series of expected returns implied by the survey provided by the Adam et al.

(2021). The difference between the fractions of bullish and bearish investors from the AAII sentiment survey is obtained from the American Association of Individual Investors website. The median one-year expected return from the Graham-Harvey survey of CFOs is obtained from the Federal Reserve Bank of Richmond. The one-year individual investor stock market confidence index is from Yale SOM website.

Sentiment measures. Finally, we relate our work to various measures of beliefs and sentiment. We construct the time series for inflation and unemployment biases following the methodology of Bhandari et al. (2024). We obtain the series of stock market sentiment index proposed by Baker and Wurgler (2007) from Jeffrey Wurgler's website. The excess bond premium measure of Gilchrist and Zakrajsek (2012) is from the Federal Reserve Board.

Table 1 reports summary statistics for selected variables. For all variables we have monthly data between January 1982 and December 2020.

4 Empirical Results

4.1 Estimated bias

We begin by examining the bias in investors' beliefs. A key advantage of our approach—which uses multivariate forecasts of market returns and analysts' forecast revisions—is that it does not assume a specific belief formation mechanism or depends on a particular proxy. This allows our estimates to offer novel insights into the properties of investor beliefs.

4.1.1 Estimated VAR

In order to capture objective predictability of market returns and of analysts' earnings forecast revisions, we opt for a parsimonious VAR model with the following five state variables: the excess market return, the analysts' forecast of market earnings growth, the revision in analysts' forecast of market earnings growth, the market price-to-dividend ratio, and the yield spread between short-term and long-term government bonds. Panel A of Table 2 reveals that all model variables possess some predictive ability. At one-month horizon, the R^2 reaches 0.03 for market return and 0.18 for revision of analysts' forecast. Panel B of Table 2 reports the VAR model's

predictive performance at longer horizons.[16,17,18]

It is noteworthy that, in the VAR, the forecast level negatively predicts subsequent forecast revisions, indicating a pattern consistent with overreaction and subsequent mean reversion as would result, for instance, from the diagnostic expectations mechanism in Bordalo et al. (2024a). This pattern is further supported by the negative coefficients estimated for the relationship between market returns and prior forecasts.

4.1.2 Bias time-variation

Examining the estimated bias series provides a more nuanced understanding of the belief distortion mechanism than relying solely on coefficients from forecast error regressions. Panel A of Figure 1 plots the bias $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ implied by the estimated VAR, alongside the market price-to-dividend ratio. The correlation between the bias and the price-to-dividend ratio is 0.32 (0.46 for changes). This positive correlation points to a pro-cyclical bias and is consistent with the notion that investors overreact to information on average.

That said, the positive correlation between the bias and the price-to-dividend ratio is primarily driven by the 19992001 Dot-com bubble, during which both market valuations and investor bias increased dramatically. At other times, we observe a different pattern. For instance, an optimistic bias can arise during downturns, consistent with underreaction. This phenomenon is most evident during the Global Financial Crisis: our estimates indicate that investors underestimated the crisis' impact on long-term cash-flow growth, attributing most of the drop in market valuation to an increase in discount rates. This finding aligns with Bianchi et al. (2024) who argue that investors were excessively optimistic about catch-up growth in the aftermath of the crisis.

[16]Including additional state variables, namely the small-stock value spread and the corporate bond default yield spread used in Campbell and Vuolteenaho (2004) and Campbell et al. (2013), does not considerably improve our VAR model's predictive ability. That said, our results remain robust when we consider these additional predictors.

[17]Appendix Table A-2 presents the results when we replace the forecast of cash flow growth calculated using equation (17) with those obtained solely from analysts' forecast of short-term earnings growth and an estimate of growth persistence, as per equation (18). The results align with those presented in Table 2.

[18]Appendix Figure A-3 shows the smoothed series of cash-flow news $\varepsilon_{d,t}^{\mathbb{P}}$, discount-rate news $\varepsilon_{r,t}^{\mathbb{P}}$, and belief shocks $\mathbf{e}_2^{\intercal}\mathbf{u}_{t+1}$, where cash-flow and discount-rate news are identified following Campbell and Vuolteenaho (2004). We note that the alternative approach described in Section 2.5, where we first identify cash-flow news and derive discount-rate news as the residual, produces shocks that are highly correlated with baseline, with correlations of 0.74 for cash-flow news and 0.93 for discount-rate news. This finding partially addresses the critique by Chen and Zhao (2009), who argue that directly estimating discount-rate news and deriving cash-flow news as the residual can be problematic due to the potential inheritance of misspecification errors by the cash-flow news. Our results suggest that any misspecification in our case is minimal.

4.1.3 Drivers of bias

To understand the factors driving investors' bias, we first note that earnings growth surprises explain a negligible fraction of the variation in the bias, see Panel A of Table 3. This suggests that the bias is unlikely to stem from a simple extrapolative mechanism, wherein investors overreact to realized cash-flow growth and become overly optimistic (pessimistic) during periods of strong (weak) performance.[19] Instead, the results indicate that factors beyond cash-flow news drive investors' beliefs. Combined with the findings in Section 4.1.2, this points to a more nuanced mechanism in which both overreaction and underreaction to different types of shocks contribute to the observed patterns.[20]

To shed further light on the sources of bias, we examine the relationship between our estimated bias and various measures of beliefs and sentiment proposed in prior literature. Specifically, we consider the differences between survey and VAR forecasts of inflation and unemployment rates, as constructed by Bhandari et al. (2024), the stock market sentiment index proposed by Baker and Wurgler (2006), and a measure of risk appetite in the corporate bond market proposed by Gilchrist and Zakrajsek (2012).

Panel A of Table 3 shows that the bias $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ tends to be high (low) when surveys underestimate (overestimate) future unemployment relative to a VAR forecast, which aligns with economic intuition. This finding indicates a connection between biases in macroeconomic and stock market expectations. That said, we do not find a similar statistically significant relationship for inflation, which may be due to structural shifts in the comovement of inflation with the business cycle and stock market within our sample period; see Cieslak and Pflueger (2023). Additionally, we find a positive and statistically significant relationship between our bias measure and the stock market sentiment index proposed by Baker and Wurgler (2006).

Finally, we find a positive and statistically significant relationship between the bias $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ and the excess bond premium computed by Gilchrist and Zakrajsek (2012). The excess bond

[19] For instance, in the diagnostic expectations model of Bordalo et al. (2024a), the bias can be represented as an exponentially weighted moving average of past earnings growth shocks, with weights determined by shock persistence and belief formation parameters. In Table 3, we follow the authors and use earnings surprises relative to cyclically adjusted earnings as a measure of sustained earnings growth that proxies for this moving average. Even using the exact specification and allowing the weight parameter to vary freely, we find that the model provides a poor fit to the estimated bias series.

[20] Examples of belief formation models that can generate both investor under- and overreaction include constant-gain learning in Nagel and Xu (2021), selective recall in Bordalo et al. (2020), biased perceptions of autocorrelation in Wang (2024), and non-Gaussian learning in de Silva et al. (2025). In addition, evidence of overreaction during the Dot-com bubble and of underreaction during the Global Financial Crisis aligns with non-finance behavioral models of preference-biased inference in which agents overreact to information that increases their expected utility and vice versa; see Eil and Rao (2011), Benabou and Tirole (2016), and a survey of this literature in Benjamin (2019).

premium serves a measure of the risk appetite in the corporate bond market, where a higher premium indicates lower risk appetite. Thus, our findings suggest that investors tend to be overly optimistic (pessimistic) about the stock market when the risk appetite in corporate the bond market is low (high).

One possible interpretation of this relationship is that stock-market investors underreact to signals from the corporate bond market. For instance, their expectations could remain overly optimistic compared to a forecast that fully considers worsening credit conditions, thereby resulting in a positive bias. To support this interpretation, we examine the causality between the excess bond premium and our bias measure $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$. Panel B of Table 3 shows that the excess bond premium Granger-causes the bias, but not vice versa.

Bordalo et al. (2018) argue that credit market conditions are themselves, in part, driven by distorted beliefs while Bordalo et al. (2024) conjecture that a common factor drives the sentiment in both credit and stock markets. By contrast, our results suggest that beliefs of credit and stock market investors may not always align. The interaction between belief distortions across different markets is an interesting topic a deeper investigation of which we leave to future research.

Overall, the univariate regression results show that each variable explains only a small portion of stock market bias, with the highest univariate R^2 value of 0.137 observed for the unemployment bias. The multivariate regression yields an R^2 value of 0.372, indicating that our bias measure captures additional dimensions of belief distortions that are not fully accounted for by the explanatory variables considered.

4.2 Bias and aggregate discount rates

We now examine the extent to which the related puzzles of excess stock-market volatility and market return predictability can be attributed to investor bias, as opposed to reflecting their beliefs.

4.2.1 Investor's beliefs about market returns

Panel B of Figure 1 shows the series of investor beliefs about long-run expected market return $\mathcal{F}_{r,t}^{\mathbb{S}}$ measured using equation (8) as the difference between the VAR forecast of long-run expected returns $\mathcal{F}_{r,t}^{\mathbb{P}}$, and the bias $\mathcal{B}_t^{\mathbb{P}-\mathbb{S}}$: $\mathcal{F}_{r,t}^{\mathbb{S}} = \mathcal{F}_{r,t}^{\mathbb{P}} - \mathcal{B}_t^{\mathbb{P}-\mathbb{S}}$. First, we observe that beliefs about future returns vary over time. This challenges a common simplifying assumption that investors use constant subjective discount rates and that attributes *all* of the variation in objective ex-

pected returns—i.e., all of excess volatility—to beliefs about cash-flow growth.[21] Second, we find that representative investor's beliefs are positively correlated with the VAR forecast, with a correlation of 0.69 (0.00 for changes). Nonetheless, although both the belief measure and the optimal VAR forecast are conditioned on the same information set, they often diverge. This, in turn, challenges the assumption of full-information rational expectations.

We also note that the correlation between our belief measure and the lower bound on expected market return computed by Martin (2016) from index options, also plotted on Panel B of Figure 1, is 0.60 (0.30 for changes). By contrast, the correlation between this bound and the VAR forecast is substantially lower, at 0.17 (0.04 for changes). The comparison between our measures of long-run expected market returns and the option-implied lower bound on the one-year expected market return is arguably imperfect. That said, to the extent that the Martin (2016) bound reflects investors' beliefs embedded in option prices rather than the statistical predictability of market returns, this comparison supports our interpretation of the belief measure.

Our belief measure also aligns with expected returns implied by analysts own stock price targets aggregated at the market level. Unlike earnings forecasts, however, these price targets are available only for a shorter sample beginning in 2002 and are limited to a one-year horizon, rendering the comparison imperfect. Nevertheless, we find a correlation of 0.46 (0.35 for changes). Notably, the correlation between price target-implied expected returns and the VAR forecast is lower, at 0.35 (0.08 for changes). The positive association between market return expectations derived from analysts earnings forecasts and those implied by their price targets supports our premise that investors apply the present-value framework, thereby reinforcing our interpretation of the belief measure.

Finally, it is instructive to compare our belief measure to other survey data. Surveys of expected returns vary considerably in their coverage, horizon, and methodology, which may explain their wide discrepancies regarding the volatility and cyclical properties of agents' beliefs. Our belief measure aligns most closely with expected returns implied by the Livingston survey, which includes a broad panel of forecasters, with a correlation of 0.01 (0.48 for changes). By contrast, the correlations between our measure and some other survey-based indices considered in the literature is, in fact, negative: -0.22 for the the AAII sentiment survey, -0.34 for the Graham-Harvey survey of CFOs, and -0.26 for the Shiller confidence index.[22] See Appendix

[21] Indeed, assuming that beliefs about future returns $\mathcal{F}^{\mathbb{S}}_{r,t}$ and objective cash-flow growth expectations $\mathcal{F}^{\mathbb{P}}_{d,t}$ are constant, simplifies equation (5) to $\mathcal{F}^{\mathbb{P}}_{r,t} = \mathcal{F}^{\mathbb{S}}_{d,t}$; see equation (40) in Nagel (2024). However, we demonstrate that $\mathcal{F}^{\mathbb{S}}_{r,t}$ is, in fact, time-varying.

[22] Some surveys begin late in our sample period, limiting the scope for meaningful comparison. For example, the series of market return expectations from several large asset managers, as collected by Dahlquist and Ibert

Figure A-4 for illustration. Thus, our results point to a possible tension between professional analysts' earnings forecasts and some of the surveys of expected returns. See also Bianchi et al. (2024), who make a similar point. That said, the broad alignment between our belief measure and both the Martin (2016) bound and the Livingston survey suggests that professional analysts forecasts are representative of investors beliefs. This mitigates concerns that analysts simply derive their earnings forecasts from observed asset prices, disregarding the variation in discount rates applied by investors; see Chaudhry (2025).

4.2.2 Stock price variance decomposition

A bias positively correlated with market valuations implies that the Campbell and Shiller (1988) variance decomposition will overestimate (underestimate) the fraction of stock-market volatility explained by the variation in discount rates (cash-flow growth) relative to investors' beliefs. In our sample, the decomposition under $\mathbb{P}$ attributes 98% of the variation in the price-to-dividend ratio to the variation in discount rates, aligning with the original findings by Campbell and Shiller (1988):

$$1 = \overbrace{\frac{\mathbb{C}\text{ov}[pd_t, \mathcal{F}^{\mathbb{P}}_{d,t}]}{\mathbb{V}\text{ar}\,[pd_t]}}^{0.02\ (0.48)} + \overbrace{\frac{\mathbb{C}\text{ov}[pd_t, -\mathcal{F}^{\mathbb{P}}_{r,t}]}{\mathbb{V}\text{ar}\,[pd_t]}}^{0.98\ (23.38)}.$$

Using equation (5) which states $\mathcal{B}^{\mathbb{S}-\mathbb{P}}_t = \mathcal{F}^{\mathbb{S}}_{d,t} - \mathcal{F}^{\mathbb{P}}_{d,t} = \mathcal{F}^{\mathbb{S}}_{r,t} - \mathcal{F}^{\mathbb{P}}_{r,t}$, we can re-write the decomposition as[23]

$$1 = \overbrace{\underbrace{\frac{\mathbb{C}\text{ov}[pd_t, \mathcal{F}^{\mathbb{S}}_{d,t}]}{\mathbb{V}\text{ar}\,[pd_t]}}_{0.26\ (3.83)} - \frac{\mathbb{C}\text{ov}[pd_t, \mathcal{B}^{\mathbb{S}-\mathbb{P}}_t]}{\mathbb{V}\text{ar}\,[pd_t]}}^{0.02\ (0.48)} + \overbrace{\underbrace{\frac{\mathbb{C}\text{ov}[pd_t, -\mathcal{F}^{\mathbb{S}}_{r,t}]}{\mathbb{V}\text{ar}\,[pd_t]}}_{0.74\ (10.94)} + \underbrace{\frac{\mathbb{C}\text{ov}[pd_t, \mathcal{B}^{\mathbb{S}-\mathbb{P}}_t]}{\mathbb{V}\text{ar}\,[pd_t]}}_{0.24\ (2.19)}}^{0.98\ (23.38)} \tag{19}$$

$\frac{\mathbb{C}\text{ov}[pd_t, \mathcal{B}^{\mathbb{S}-\mathbb{P}}_t]}{\mathbb{V}\text{ar}[pd_t]} = 0.24$ implies that 24 percentage points of the price-to-dividend ratio variance that the decomposition under $\mathbb{P}$ attributes to discount-rate variation is due to expected cash-flow growth variation under $\mathbb{S}$. Thus, our results indicate that, even after adjusting for bias, discount-rate variation remains a significant driver of stock-market volatility, accounting for 74% of price-to-dividend ratio variance under investors' beliefs.

(2024), begins only in 2010. The authors find that these expectations are countercyclical—a pattern that is also true for our belief measure over a longer sample. It is important to note, however, that countercyclicality does not imply that asset managers expectations are necessarily rational.

[23] De la O and Myers (2024) derive alternative identities that link price ratiossuch as the priceearnings and pricedividend ratiosto subjective expectations and expectation errors. They find that systematic errors in long-term inflation expectations play a significant role in explaining variation in asset prices.

This finding stands in contrast to the results in De La O and Myers (2021), who argue that beliefs about cash-flow growth explain the majority of stock-market volatility. Unlike these authors, our conclusion stems from the properties of investors' bias rather than directly from surveys. Specifically, the estimated bias is only moderately pro-cyclical, resulting in a moderate adjustment to the variance decomposition. More importantly, we also differ in our definition of earnings per share. Prior accounting research—see Bradshaw and Sloan (2002) and Bradshaw (2004), among others—shows that analysts forecast earnings excluding extraordinary items. These so-called "Street" earnings are therefore the relevant benchmark for our analysis. Accordingly, we rely on this definition. Moreover, Street earnings can differ substantially from the earnings measure used by De La O and Myers (2021), which includes extraordinary itemsthis discrepancy accounts for a significant portion of the differences in our results. See also Nagel (2024) for a discussion of the pitfalls associated with including extraordinary items in earnings measures.[24]

4.2.3 Market return predictability

A natural next step is to ask whether distorted beliefs can account for the predictability in market returns. To answer this question, it is necessary to disentangle the component of predictability stemming from belief distortions affecting asset valuations from the component consistent with investor's beliefs. In doing so, we extend the analysis of Bordalo et al. (2024a) to incorporate time-varying beliefs about future market returns.[25]

Panel B of Table 2 shows that the VAR forecast explains 3% of market excess returns at the one-month horizon, 24% at the one-year horizon, and 51% in the long-run limit. However, the part of this predictability that is due to distorted beliefs cannot be readily gauged from predictive regressions because belief distortions may not be orthogonal to other factors driving expected returns. To disentangle the contribution of distorted beliefs we note that equation (8) implies a decomposition of expected return variance into the covariance with belief and the covariance with bias:

$$1 = \underbrace{\frac{\mathbb{C}\text{ov}[\mathcal{F}^{\mathbb{P}}_{r,t}, \mathcal{F}^{\mathbb{S}}_{r,t}]}{\mathbb{V}\text{ar}\left[\mathcal{F}^{\mathbb{P}}_{r,t}\right]}}_{0.59\ (6.39)} + \underbrace{\frac{\mathbb{C}\text{ov}[\mathcal{F}^{\mathbb{P}}_{r,t}, \mathcal{B}^{\mathbb{P}-\mathbb{S}}_{t}]}{\mathbb{V}\text{ar}\left[\mathcal{F}^{\mathbb{P}}_{r,t}\right]}}_{0.41\ (4.48)}. \tag{20}$$

[24] Appendix A.4 replicates the analysis using the price-to-earnings ratio and finds similar results, although the precise definition of earnings becomes more consequential in that context. Overall, our results are robust across various valuation measures, including the Shiller CAPE, the price-to-earnings ratio based on Street earnings, and the price-to-earnings ratio constructed from Compustat net income excluding non-I/B/E/S items. Importantly, the fact that our findings hold even when using the Street earnings-based P/E ratiowhich is less persistent than the price-to-dividend or CAPE ratiossuggests that our conclusions are not driven by long-term trends in the data.

[25] Specifically, we relax the assumption in equation (5) in Bordalo et al. (2024a); see also their footnote 15.

This decomposition shows that 41% of long-run market return predictability uncovered by the VAR model can be attributed to distorted beliefs. While belief distortions account for a substantial portion of the objective predictability in market returns, they do not explain it entirely. The remaining 59% represent the variation in expected market returns that is consistent with the representative investor's beliefs, reflecting the significant time-variation in subjective discount rates.

4.3 Bias and the cross-section of stock returns

We now investigate whether distorted beliefs influence the pricing of risk in the cross-section of expected stock returns. To this end, we conduct cross-sectional asset pricing tests that incorporate bias shocks ($\varepsilon_{\mathcal{B},t}$). While these shocks manifest themselves as discount-rate risk in the data, they actually represent cash-flow risk from the investor's perspective, and vice versa. We test the significance of these shocks and assess the improvement in the model's pricing performance when these shocks are included as a way to gauge the wedge between pricing under investor's beliefs and the observed risk-return relationship.

4.3.1 Baseline cross-section

We start by testing an ICAPM-type linear factor model that includes cash-flow news ($\varepsilon^{\mathbb{P}}_{d,t}$) and discount-rate news ($\varepsilon^{\mathbb{P}}_{r,t}$) and bias shocks ($\varepsilon_{\mathcal{B},t}$) as factors. Our test assets comprise a standard set of Fama-French portfolios sorted by market capitalization (ME), book-to-market ratio (BE/ME), and past returns. Following Campbell and Vuolteenaho (2004), we also construct a second set of portfolios sorted by past risk loadings using VAR state variables.[26] Using these 51 test assets—30 size-, book-to-market-, and momentum-sorted portfolios, 20 risk-sorted portfolios, and the market excess return—we evaluate the performance of the traditional two-factor ICAPM with cash-flow and discount-rate factors (columns 1-2 and 5-6 in Table 4), comparing it with the model that includes the bias shock. Each model is estimated in two forms: one with an unrestricted zero-beta rate (odd columns) and another with a restricted zero-beta rate equal to the Treasury bill rate (even columns). In both cases, we allow for unrestricted risk prices for cash-flow, discount-rate, and bias shocks. The first set of results (labeled Baseline) combines short- and long-term analysts' earnings forecasts as specified in equation (17), while the sec-

[26]The risk loadings are estimated by regressing each stock in the CRSP database, excluding the smallest five percent (by market equity), on market returns, as well as changes in term and value spreads. Similarly to Campbell and Vuolteenaho (2004) we exclude the (changes in) price-to-dividend ratio from this regression due to its high collinearity with market returns.

ond set of results uses solely short-term analysts' earnings forecasts and an estimate of growth persistence, as specified in equation (18).

Table 4 shows that over the 1982-2020 period, the traditional two-factor ICAPM explains only a small fraction of the cross-section of stock returns, with an R^2 of approximately 3%. Introducing bias shocks considerably enhances the pricing performance, with models in columns (3) and (7) achieving R^2 values of 36% and 28%, respectively. Moreover, we cannot reject that null hypothesis that $R^2 = 1$. However, the χ^2 statistic rejects the null hypothesis that all pricing errors are jointly zero, implying that the two-factor model augmented with beliefs does not fully explain the cross-section of returns on our 51 portfolios. Figure 2 visually summarizes these results by plotting the average realized returns of test portfolios against model-fitted values. While the risk-sorted, momentum, and, to a lesser extent, book-to-market portfolios align well along the 45-degree line—indicating that their returns are well-explained by the model—the size portfolios are scattered across the middle of the plot, suggesting that their fitted returns exhibit meaningful variation, whereas their realized returns do not.

The estimated risk price on bias shocks is significant with both a restricted zero-beta rate and an unrestricted Treasury bill rate, irrespective of whether analysts' long-term earnings forecasts are used. By contrast, estimates for discount-rate and cash-flow news exhibit larger standard errors. When using only short-term analyst forecasts, the risk price per unit of standard deviation in bias exposures is about 7% per year with an unrestricted zero-beta rate.[27] The risk price increases when combining long-term forecasts with short-term ones to compute beliefs.[28]

The magnitude of risk prices also provides insight into the representative investor's risk aversion, as can be seen from equation (10). The implied coefficient of relative risk aversion, based on the estimated risk prices of cash-flow and bias shocks, is calculated as $\frac{0.096}{0.096-0.055} = 2.34$ in column (3) and $\frac{0.067}{0.067-0.029} = 1.78$ in column (7), both of which are well within the range of generally accepted values.

4.3.2 Industry portfolios

Adding 10 Fama-French industry portfolios to the set of tests assets does not diminish the model's pricing performance, with cross-sectional R^2 remaining at 29%. This is illustrated on

[27] The standard deviation of belief betas is 0.2028, leading to a calculation of $0.029 \times 0.2028 \times 1200 = 7.13\%$.

[28] Finally, we note that results in Table 4 are robust to including extraordinary items in earnings. Appendix Table A-3 replicates the results from Table 4 using this alternative measure of earnings. Notably, bias shocks remain statistically significant across specifications. The models in columns (3) and (7) achieve higher R^2 values than in Table 4, supporting the notion that including extraordinary items tends to overestimate belief distortions. In sum, our cross-sectional asset pricing results remain robust when using both short-term earnings forecasts and earnings that include extraordinary items.

Panel A of Figure 3, which plots average realized returns against model-fitted values for the industry portfolios, alongside the other 51 portfolios we consider. As shown in Panel B of Figure 3, the pricing of industry portfolios largely reflects their exposure to bias shocks, with business equipments (HiTec) and consumer durables (Durbl) showing the highest exposure, and oil, gas and coal extraction and products (Enrgy) and utilities (Utils) showing the lowest.

4.3.3 Results with supervised PCA

Although our model incorporating beliefs is quite successful in explaining this particular cross-section of average returns, an asset pricing model can spuriously explain the average returns of characteristics-sorted portfolios related to average returns if premia are unconstrained by theory; see Daniel and Titman (1997). To alleviate this concern, we follow the supervised-PCA approach of Giglio et al. (2024), which also accommodates weak latent factors.

We present these results for both bias shocks ($\varepsilon_{\mathcal{B},t}$) and belief shocks ($\mathbf{e}_2^\intercal \mathbf{u}_t$). By construction, the difference between these two shocks is equal to cash-flow news. Thus, considering beliefs shocks can be seen a robustness test to our estimate of cash-flow news.

We use data from Chen and Zimmermann (2022), which includes a large number of equity portfolios sorted by characteristics. For each plausible number of latent factors, p, in our analysis, we have a tuning parameter to select: the number of assets chosen. Following Giglio et al. (2024), the first half of the sample (training period) is used to choose the tuning parameters and estimate the risk premium. The second half of the sample (evaluation period) is used to evaluate the out-of-sample performance of the estimator and the choice of the tuning parameter. Motivated by the scree plot, we present results for p equal to 5, 7, and 11, demonstrating the robustness of our findings across a range of model dimensions.

Table 5 presents the results. The columns labeled "Baseline" report outcomes based on analysts forecasts of both short-term and long-term earnings growth. The columns labeled "Short-term forecasts only" show results using analysts forecasts of short-term earnings growth. The top panel covers bias shocks, while the bottom panel addresses belief shocks. For each choice of latent factors ($p = 5, 7,$ and 11), we report the SPCA risk-premium estimate and the number of assets selected by SPCA. In these estimates, asset selection is driven solely by the respective shock.

The SPCA estimates of the bias (belief) premia for $p = 5, 7, 11$ are, respectively, 36, 56, and 78 (17, 30, and 46) basis points per month, in the baseline case that uses both short- and long-term forecasts. The corresponding premia when using only short-term earnings forecasts are similar in magnitude, and equal to 54, 80, and 109 (79, 60, and 83) basis points. These

estimates are stable across specifications and statistically significant. Importantly, these values align closely with the estimates in Table 4. For instance, in the baseline case, the SPCA mimicking portfolio with 11 latent factors has a loading of 0.186 on the non-tradable bias factor. This results in a risk premium of $0.055 \times 0.186 = 102$ basis points (where 0.055 is the risk price from Table 4), which is smaller but close to the average SPCA excess return. Similarly, when considering the bias shock using only short-term forecasts, the SPCA mimicking portfolio with 11 latent factors has a loading on the non-tradable bias factor of 0.396, delivering a risk premium of $0.029 \times 0.396 = 115$ basis points (where 0.029 is the risk price from Table 4) which is slightly smaller but close to the average SPCA excess return.

To better understand the performance of the SPCA estimator, we can examine the out-of-sample R^2. Note that it is well known in the literature that it is difficult to hedge nontradable factors, like consumption or IP growth, in equity markets. Furthermore, we should not expect large R^2 since SPCA attempts to build a hedging portfolio for the target—in our case bias or beliefs—with factors that must also explain covariation among the universe of test assets. Therefore, an advantage of the SPCA approach is that the hedging portfolio is able to avoid fitting the "measurement error" component in the target, which can be thought of measurement error for nontradable factors like ours.

Interestingly, the out-of-sample R^2 for the baseline bias shock, constructed using both long- and short-term earnings forecasts, ranges from about 4% to 6%, while it is 3% to 4% when using only short-term forecasts. This result has both economic and statistical interpretations. Economically, the positive, albeit modest, out-of-sample R^2 indicates the portfolio built by SPCA for beliefs and biases offers good hedging ability. Statistically, it confirms that the asset selection made by SPCA in the training sample remains valid out of sample. However, the large number of assets selected (ranging from 600 to 950) highlights the challenge of hedging beliefs or biases—similar to most macro factors—using equity markets.

In Table 6, we analyze which assets are selected when extracting latent factors. The portfolio names follow Chen and Zimmermann (2022), with numbers indicating the quintile or decile of the characteristic. For clarity, we group portfolios into six economic categories based on the firm characteristics used to construct them: Intangibles, Investment, Momentum, Profitability, Trading Frictions, Value vs. Growth, and Other.[29]

Focusing on Panel A, SPCA selects assets with the highest correlation to the bias shock to extract the first latent factor. The table reveals that these assets are associated with value, trading frictions, and investment. The highest correlation is achieved by Duration_2 (the second-lowest duration portfolio), with a correlation of 0.58. Interestingly, several of the top assets chosen

[29]When the factor is included in Hou et al. (2020), we follow their classification.

to hedge the bias shock, such as Duration_2, Investment_3, and Investment_4, are also selected to hedge the belief shock.

The remainder of the table shows assets selected in different iterations. In the second iteration, after orthogonalizing beliefs and test assets to the first factor, selected assets are mostly related to profitability and momentum. In the third iteration, portfolios sorted on share issuance and repurchases play an important role in hedging risk. This aligns with the model by Daniel et al. (2020), which proposes using a long-horizon factor that exploits managers' decisions to issue or repurchase equity in response to persistent mispricing.

4.3.4 Subjective risk and returns

Thus far, we have examined the relationship between objective returns and subjective risk. As stock-specific bias $\left(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}}\right) r_{i,t+1}^e$ may introduce additional noise in equation (11), our empirical tests provided only a lower bound on the role of investor bias in the assessment of risk. Instead, we now investigate the relationship between subjective returns and risk. This approach requires additional survey data to measure investors' beliefs about individual stock returns but results in a more accurate evaluation of the risk-return trade-off.

To this end, we follow Jensen (2024) and use the one-year consensus dividend per share (DPS) forecasts and consensus price targets from IBES to construct single stock expected total returns in month t as:[30]

$$\mathbb{E}_t^{\mathbb{S}} r_{i,t,t+12}^e = \frac{\mathbb{E}_t^{\mathbb{S}}\left[P_{t+12}\right] + \mathbb{E}_t^{\mathbb{S}}\left[DPS_{t+12}\right]}{P_{t-1}} - 1$$

This is similar to Adam et al. (2017) and Nagel and Xu (2023) who adjust these price growth expectations with the dividend yield to arrive at return expectations. We then aggregate this subjective expected returns from the stock level to the portfolio level. We sort stocks into portfolios based on the same characteristics used in Table 4, compute subjective expected excess returns using I/B/E/S data, and conduct cross-sectional tests analogous to those in Table 4. Similar to Jensen (2024), we convert annual subjective return forecast to monthly horizon using geometric compounding:

$$\mathbb{E}_t^{\mathbb{S}} r_{i,t+1}^e = \left(1 + \mathbb{E}_t^{\mathbb{S}} r_{i,t,t+12}^e\right)^{1/4} - 1$$

A potential concern when using I/B/E/S data is its coverage relative to the CRSP/Compustat universe. To address this, Appendix Table A-4 presents descriptive statistics showing that

[30] See Appendix A.3 for details on the data construction.

I/B/E/S coverage is strong. In particular, coverage exceeds 90% in terms of both the number of stocks and market capitalization for all portfolios considered in Table 4, with the exception of the smallest market equity (ME) quintile. As a result, we exclude this quintile from our analysis going forward.

Table 7 Panel A replicates the results from Table 4, but restricts the sample to firms for which we observe both monthly median price targets (PTG) from the I/B/E/S U.S. Unadjusted Summary Price Targets files and monthly median forecasts of dividends per share (DPS) from sell-side analysts. Because both PTG and DPS forecasts are available starting in May 2002, the sample period begins at that time. The results show that even within this shorter sample, the bias shock continues to help explain the cross-section of objective returns. While the explanatory power of the pure cash-flow beta shock increases, the inclusion of the bias shock raises the cross-sectional R^2 by approximately 40%, from 33% in column (1) to 46% in column (3). Although the GMM t-statistic on the bias shock is 1.4, this is largely driven by the momentum portfolio. Excluding the momentum portfolios raises the cross-sectional R^2 in column (3) to 57%, and the t-statistic on the bias shock increases to 1.99.

Panel B of Table 7 shifts the focus from explaining average historical returns to explaining subjective returns. While the right-hand-side variablescovariances with cash-flow news, discount rate news, and the bias shockremain the same, the left-hand side now reflects investors expectations rather than realized outcomes. Two results emerge. First, in column (1), cash-flow and discount rate news together explain a substantial share of the variation in subjective expected returns across portfolios, with an R^2 of 66%. This finding aligns with Jensen (2024), who show that traditional asset pricing models like the CAPM perform well—indeed better than more recent multi-factor models—in explaining subjective expected returns from I/B/E/S. More importantly, in column (3), we observe that bias shocks are priced and render the discount rate news statistically insignificant. This suggests that bias plays a central role in shaping investors' subjective return expectations. The increase in the R^2 in column (3) from 46% in panel A to 66% in Panel B aligns with our premise that stock-specific bias introduces additional noise in equation (11) as well as with the findings in Bordalo et al. (2024b). A similar pattern emerges when the analysis is restricted to short-term forecasts: in column (5), discount rate shocks help explain the cross-section of subjective returns, but once bias shocks are included in column (7), they become insignificant.

5 Conclusion

We show that accounting for investors' distorted beliefs—i.e., the wedge between between their beliefs and objective expectations—provides new insights into apparent empirical puzzles observed in both the time series and the cross-section of expected stock returns. Our findings offer compelling evidence for the important role played by investors' expectational biases in the stock market. Furthermore, our results suggest that investors' beliefs about the stock market are interconnected to their beliefs about the credit market and the macroeconomy. Exploring the interaction between beliefs across different markets is an interesting avenue for future research. The analytical framework developed in this paper can be instrumental in pursuing this line of inquiry.

Table 1: **Summary Statistics.** This Table presents summary statistics of our state variables in the VAR estimations. Note that we do not report the mean and the median of the two alternative definitions of $\mathcal{F}^{\mathbb{S}}_{d,t}$ as they are simply calibrated to the unconditional mean and median of the price-to-earnings ratio in the data as discussed in the Section 3.1. Data is monthly from January 1982 through December 2020.

Variable	Mean	Median	Std.	Min	Max
Market return, r^e_t	0.0085	0.0105	0.0435	-0.1985	0.1401
Price-to-dividend ratio, pd_t	3.7803	3.8858	0.3716	2.7533	4.5236
Term spread, ty_t	2.2794	2.3400	1.2681	-0.4100	4.5500
Variables according to Bordalo et al. (2024a)					
Forecast, $\mathcal{F}^{\mathbb{S}}_{d,t}$	-	-	0.1585	2.1399	2.8645
Short-term component of $\mathcal{F}^{\mathbb{S}}_{d,t}$	0.1812	0.1638	0.0790	0.0123	0.4446
Long-term component of $\mathcal{F}^{\mathbb{S}}_{d,t}$	0.1218	0.1174	0.0170	0.0953	0.1828
Forecast revision, $\varepsilon^{\mathbb{S}}_{d,t}$	0.0007	0.0023	0.0454	-0.1786	0.2335
Variables according to De La O and Myers (2021)					
Forecast, $\mathcal{F}^{\mathbb{S}}_{d,t}$	-	-	0.1399	2.0795	2.8447
Forecast revision, $\varepsilon^{\mathbb{S}}_{d,t}$	0.0003	0.0014	0.0666	-0.2895	0.3430
Additional variables					
Value spread, vs_t	1.5250	1.4949	0.1958	1.1691	2.2310
Default spread, def_t	1.0505	0.9300	0.4332	0.5500	3.3800

Table 2: **VAR model.** Panel A of this table reports the coefficients on the explanatory variables in the VAR model. Each row corresponds to a different equation of the model. The variables include the market excess return (r_t^e), the revisions in analysts' forecast of market earnings growth ($\varepsilon_{d,t}^{\mathbb{S}}$), analysts' forecast of market earnings growth ($\mathcal{F}_{d,t}^{\mathbb{S}}$), the market price-to-dividend ratio (pd_t), and the yield spread between short-term and long-term government bonds (ty_t). Ordinary least squares t-statistics are reported in parentheses below the coefficients. The last column reports the R^2. Panel B reports the fraction of the variation in excess market return and in the revisions in analysts' forecast of market earnings growth at H-month horizon explained by the VAR forecast computed from the estimated VAR model. Analysts' forecast combines short-term and long-term earnings growth forecasts as specified in equation (17). Data are monthly from January 1982 through December 2020.

Panel A: model equations

	r_t^e	$\varepsilon_{d,t}^{\mathbb{S}}$	$\mathcal{F}_{d,t}^{\mathbb{S}}$	pd_t	ty_t	R^2

Panel B: predictability at H-month horizon

	$H=1$	$H=3$	$H=12$	$H=120$	$H\to\infty$
$\frac{\mathbb{V}\text{ar}[\mathbb{E}_t^{\mathbb{P}}\sum_{h=0}^{H-1}\rho^h r_{t+1+h}^e]}{\mathbb{V}\text{ar}[\sum_{h=0}^{H-1}\rho^h r_{t+1+h}^e]}$	0.029	0.077	0.239	0.536	0.513
$\frac{\mathbb{V}\text{ar}[\mathbb{E}_t^{\mathbb{P}}\sum_{h=0}^{H-1}\rho^h \varepsilon_{d,t+1+h}^{\mathbb{S}}]}{\mathbb{V}\text{ar}[\sum_{h=0}^{H-1}\rho^h \varepsilon_{d,t+1+h}^{\mathbb{S}}]}$	0.180	0.225	0.540	0.535	0.243

Table 3: **Sources of stock-market bias.** Panel A reports the slope coefficients from regressions of the bias $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ on the earnings surprises relative to cyclically adjusted earnings computed following Bordalo et al. (2024a) (Earnings surprises), the differences between survey and VAR forecasts of, respectively, inflation (Inflation bias) and unemployment (Unemployment bias) rates computed following Bhandari et al. (2024), the Baker and Wurgler (2006) stock market sentiment index (Sentiment), and the Gilchrist and Zakrajsek (2012) excess bond premium (Excess bond premium). Newey and West (1987, 1994) t-statistics are reported in parentheses. Panel B reports the F-statistic and the associated p-values from the test of Granger causality between the bias $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ and the excess bond premium (EBP). The VAR for the causality test includes 6 lags chosen by the Akaike information criterion. Results use the analysts' forecast of both short-term and long-term earnings growth combined as specified in equation (17). Data are monthly and run from January 1982 to December 2020.

Panel A: Bias $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$						
Earnings surprises	0.202					
	(3.202)					
Inflation bias		-0.019				-0.005
		(-0.849)				(-0.183)
Unemployment bias			-0.104			-0.115
			(-3.276)			(-3.783)
Sentiment				0.148		0.143
				(3.305)		(4.745)
Excess bond premium					0.146	0.149
					(2.507)	(4.394)
R^2	0.018	0.004	0.137	0.128	0.094	0.372

Panel B: Granger causality		
	F-stat.	p-val.
Bias does not Granger cause EBP	1.603	0.145
EBP does not Granger cause Bias	3.957	0.001

Table 4: **ICAPM.** This table reports the results of the cross-sectional regression of mean excess portfolio returns on portfolio betas estimated in the first-pass univariate regressions. The model is estimated using 51 portfolios: 20 risk portfolios, 10 Fama-French book-to-market ranked portfolios, 10 Fama-French size ranked portfolios, 10 momentum ranked portfolios, and the market portfolio. The table reports the estimates of the constant term and the factor risk premia for cash-flow news ($\varepsilon^{\mathbb{P}}_{d,t}$), discount-rate news ($\varepsilon^{\mathbb{P}}_{r,t}$), and bias shock ($\varepsilon_{\mathcal{B},t}$). t-statistics based on the GMM-VARHAC standard errors for these estimates are reported in the parentheses. The table also reports the R^2 of the cross-sectional regression and its p-value under the null that $R^2 = 1$. Finally, the table reports the statistic and the associated p-value of the chi-squared test of the null hypothesis that all pricing errors are jointly zero. Columns (1)-(4) report the results in which we use the analysts' forecast of both short-term and long-term earnings growth as specified in equation (17). Columns (5)-(8) report the results in which we use analysts' forecast of short-term earnings growth and an estimate of growth rate persistence as specified in equation (18). Data are monthly from January 1982 through December 2020.

	Baseline				Short-term forecast only

Table 5: **Pricing of bias and belief shocks.** This table reports the risk premia for (nontradable) bias shocks ($\varepsilon_{\mathcal{B},t}$) and belief shocks ($\mathbf{e}_2^\intercal \mathbf{u}_t$) estimated using the supervised principal component analysis (SPCA) procedure proposed by Giglio et al. (2024). The columns report, for different number of latent factors, the estimated risk premia (in percent per month, computed in the training period), the associated t-statistic (in parentheses below), the number of assets selected by SPCA, and the out of sample R^2 (OOS R^2). The universe of assets consists of Chen and Zimmermann (2022) portfolios augmented with 49 industry portfolios. Columns denoted Baseline report the results in which we use the analysts' forecast of both short-term and long-term earnings growth as specified in equation (17). Columns denoted Short-term forecasts only report the results in which we use analysts' forecast of short-term earnings growth and an estimate of growth rate persistence as specified in equation (18). Data are monthly from January 1982 through December 2020.

Bias shocks, $\varepsilon_{\mathcal{B},t}$						
	Baseline			Short-term forecasts only		
# factors	Premium	# assets	OOS R^2	Premium	# assets	OOS R^2
5	36	850	0.046	54	750	0.042
	1.565			2.077		
7	56	950	0.064	80	900	0.035
	2.333			3.077		
11	78	950	0.043	109	950	0.030
	3.000			3.759		
Belief shocks, $\mathbf{e}_2^\intercal \mathbf{u}_t$						
	Baseline			Short-term forecasts only

11	46	950	0.122	83	950	0.101
	2.556			3.320		

Table 6: **Latent factor portfolios.** This table reports for bias shocks ($\varepsilon_{\mathcal{B},t}$) and belief shocks ($\mathbf{e}_2^\intercal \mathbf{u}_t$) the top-10 portfolios selected by the supervised principal component analysis (SPCA) procedure proposed by Giglio et al. (2024) when extracting the latent factors. Portfolios are sorted by the absolute value of the correlation with shocks. For each latent factor from 1 to 3, the table reports the economic category and the names of the portfolios selected, and the absolute value of the correlation. Naming convention for the portfolios follows Chen and Zimmermann (2022). Results use the analysts' forecast of both short-term and long-term earnings growth combined as specified in equation (17). Data are monthly from January 1982 through December 2020.

A Bias

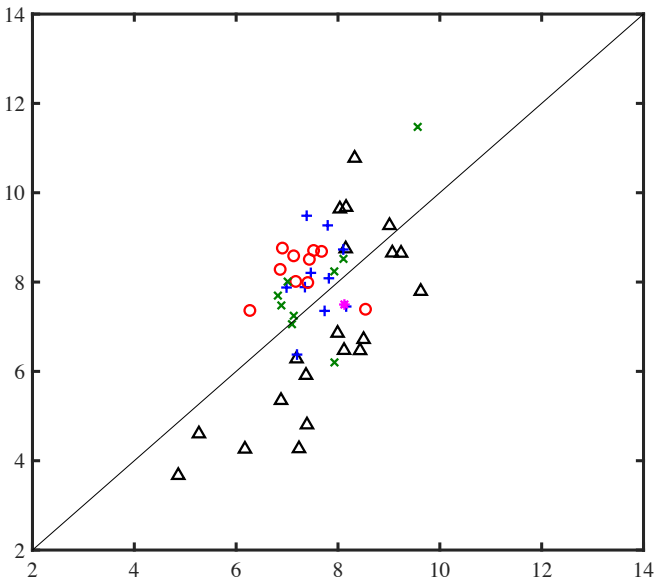

B Expected market returns

Figure 1: **Bias and beliefs**: Panel A plots the bias $\mathcal{B}_t^{\mathbb{S}-\mathbb{P}}$ estimated as the long-run predictable component of analysts' forecast revisions as per equation (7). The panel also shows the market price-to-dividend ratio. Shaded areas correspond to NBER recessions. Panel B plots the VAR forecast of the long-term market returns $\mathcal{F}_{r,t}^{\mathbb{P}}$ and the belief about long-term market returns $\mathcal{F}_{r,t}^{\mathbb{S}}$ obtained as the VAR forecast adjusted for the bias using equation (5). Results use the analysts' forecast of both short-term and long-term earnings growth combined as specified in equation (17). The panel also shows the lower bound on expected market return (at one-year horizon) from Martin (2016).

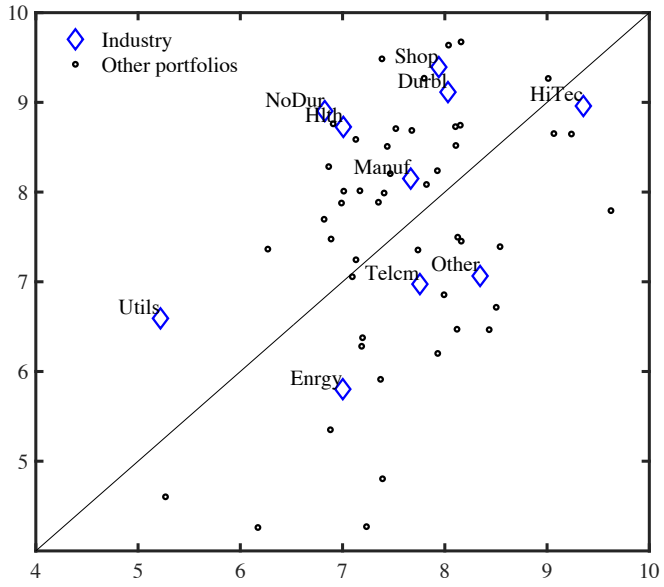

A ICAPM

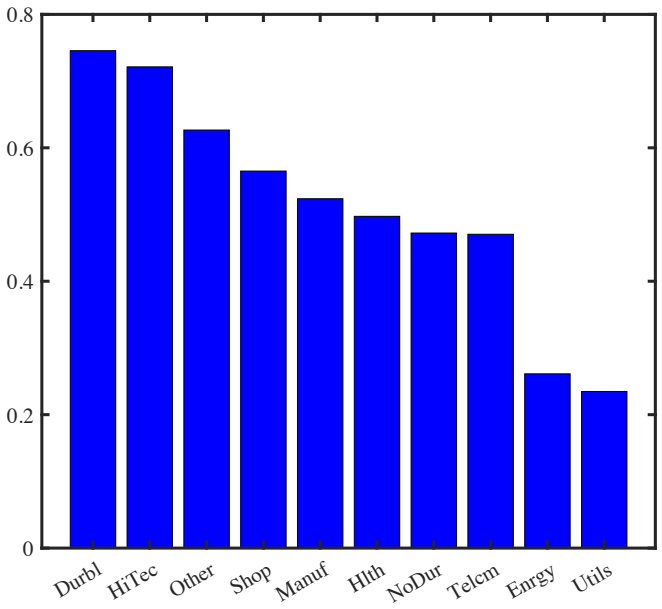

B ICAPM with distorted beliefs

Figure 2: **Performance of ICAPM with distorted beliefs**: The figure plots the predicted mean excess returns (x-axis) against the realized mean excess returns (y-axis) for 51 portfolios including 20 risk portfolios, 10 Fama-French book-to-market ranked portfolios, 10 Fama-French size ranked portfolios, 10 momentum ranked portfolios, and the market portfolio. Predicted returns correspond to regressions (1) and (3) in Table 4. In panel A corresponding to regression (1), the factors are cash-flow news ($\varepsilon^{\mathbb{P}}_{d,t}$) and discount-rate news ($\varepsilon^{\mathbb{P}}_{r,t}$); in panel B corresponding to regression (3), the factors are cash-flow news ($\varepsilon^{\mathbb{P}}_{d,t}$), discount-rate news ($\varepsilon^{\mathbb{P}}_{r,t}$), and the bias shock ($\varepsilon_{\mathcal{B},t}$).

A Predicted and realized returns

B Betas to bias risk

Figure 3: **Pricing of industry portfolios**: Panel A plots the predicted mean excess returns (x-axis) against the realized mean excess returns (y-axis) for 10 Fama-French industry portfolios—namely, consumer nondurables (NoDur), consumer durables (Durbl), manufacturing (Manuf), oil, gas and coal extraction and products (Enrgy), Business Equipment (HiTec), telephone and television transmission (Telcm), wholesale, retail, and some services (Shops), healthcare, medical equipment, and drugs (Hlth), Utilities (Utils), and other (Other)—and 51 portfolios (Other portfolios) we use in our baseine analysis. Predicted returns correspond to a version of the regressions in column (3) of Table 4 that includes industry portfolios. Panel B plots the betas of 10 industry portfolios to the bias shocks. Results use the analysts' forecast of both short-term and long-term earnings growth combined as specified in equation (17).

Appendix

A.1 Proofs

Proof of the result in Section 2.3. Consider identity (3) with expectations taken under $\mathbb{S}$:

$$r_{t+1} - \mathbb{E}_t^{\mathbb{S}} r_{t+1} = \varepsilon_{d,t+1}^{\mathbb{S}} - \varepsilon_{r,t+1}^{\mathbb{S}}.$$

Pre-multiplying by ρ^h and summing over $h = 0, ..., H-1$, we have

$$\sum_{h=0}^{H-1} \rho^h r_{t+1+h} - \sum_{h=0}^{H-1} \rho^h \mathbb{E}_{t+h}^{\mathbb{S}} r_{t+1+h} = \sum_{h=0}^{H-1} \rho^h \varepsilon_{d,t+1+h}^{\mathbb{S}} - \sum_{h=0}^{H-1} \rho^h \varepsilon_{r,t+1+h}^{\mathbb{S}}.$$

Note that

$$\begin{aligned}
\sum_{h=0}^{H-1} \rho^h \mathbb{E}_{t+h}^{\mathbb{S}} r_{t+1+h} - \sum_{h=0}^{H-1} \rho^h \varepsilon_{r,t+1+h}^{\mathbb{S}} &= \sum_{h=0}^{H-1} \left(\rho^h \mathbb{E}_{t+h}^{\mathbb{S}} r_{t+1+h} - (\mathbb{E}_{t+1+h}^{\mathbb{S}} - \mathbb{E}_{t+h}^{\mathbb{S}}) \sum_{k=h+1}^{\infty} \rho^k r_{t+1+k} \right) \\
&= \mathbb{E}_t^{\mathbb{S}} r_{t+1} - \mathbb{E}_{t+1}^{\mathbb{S}} \sum_{k=1}^{\infty} \rho^k r_{t+1+k} + \mathbb{E}_t^{\mathbb{S}} \sum_{k=1}^{\infty} \rho^k r_{t+1+k} \\
&\quad + \rho \mathbb{E}_{t+1}^{\mathbb{S}} r_{t+2} - \mathbb{E}_{t+2}^{\mathbb{S}} \sum_{k=2}^{\infty} \rho^k r_{t+1+k} + \mathbb{E}_{t+1}^{\mathbb{S}} \sum_{k=2}^{\infty} \rho^k r_{t+1+k} \\
&\quad + ... \\
&= \mathbb{E}_t^{\mathbb{S}} \sum_{k=0}^{\infty} \rho^k r_{t+1+k} - \mathbb{E}_{t+H}^{\mathbb{S}} \sum_{k=H}^{\infty} \rho^k r_{t+1+k}.
\end{aligned}$$

Breaking $\mathbb{E}_t^{\mathbb{S}} \sum_{k=0}^{\infty} \rho^k r_{t+1+k}$ into $\mathbb{E}_t^{\mathbb{S}} \sum_{k=0}^{H-1} \rho^k r_{t+1+k} + \mathbb{E}_t^{\mathbb{S}} \sum_{k=H}^{\infty} \rho^k r_{t+1+k}$, taking conditional expectations under $\mathbb{P}$ and re-arranging, one obtains:

$$\overbrace{\underbrace{\mathbb{E}_t^{\mathbb{P}} \sum_{k=0}^{H-1} \rho^k r_{t+1+k}}_{\to \mathcal{F}_{r,t}^{\mathbb{P}} \text{ as } H \to \infty}}^{\text{objective}} = \overbrace{\underbrace{\mathbb{E}_t^{\mathbb{S}} \sum_{k=0}^{H-1} \rho^k r_{t+1+k}}_{\to \mathcal{F}_{r,t}^{\mathbb{S}} \text{ as } H \to \infty}}^{\text{belief}} + \overbrace{\underbrace{\mathbb{E}_t^{\mathbb{P}} \sum_{k=0}^{H-1} \rho^h \varepsilon_{d,t+1+k}^{\mathbb{S}}}_{\to \mathcal{B}_t^{\mathbb{P}-\mathbb{S}} \text{ as } H \to \infty} + \underbrace{(\mathbb{E}_t^{\mathbb{S}} - \mathbb{E}_t^{\mathbb{P}}) \mathbb{E}_{t+H}^{\mathbb{S}} \sum_{k=H}^{\infty} \rho^k r_{t+k+1}}_{\to 0 \text{ as } H \to \infty}}^{\text{belief distortion}}.$$

Proof of the result in Section 2.4. Denote $s = \frac{d\mathbb{S}}{d\mathbb{P}}$ the Radon-Nikodym derivative that describes the relationship between two equivalent, i.e. absolutely continuous with respect to each other, probability measures $\mathbb{S}$ and $\mathbb{P}$. Hence, we have $\mathbb{E}^{\mathbb{S}}(x) = \mathbb{E}^{\mathbb{P}}(sx)$ and $\mathbb{E}^{\mathbb{P}}(s) = 1$. Now,

$$\begin{aligned}
\mathbb{C}\text{ov}^{\mathbb{S}}(x, y) &= \mathbb{E}^{\mathbb{S}}(xy) - \mathbb{E}^{\mathbb{S}}(x)\mathbb{E}^{\mathbb{S}}(y) \\
&= \mathbb{E}^{\mathbb{P}}(sxy) - \mathbb{E}^{\mathbb{P}}(sx)\mathbb{E}^{\mathbb{P}}(sy).
\end{aligned}$$

Using the results in Bohrnstedt and Goldberger (1969), we can re-write the first term as

$$\begin{aligned}
\mathbb{E}^{\mathbb{P}}(sxy) &= \mathbb{E}^{\mathbb{P}}(s)\mathbb{E}^{\mathbb{P}}(xy) + \mathbb{C}\text{ov}^{\mathbb{P}}(s, xy) \\
&= \mathbb{E}^{\mathbb{P}}(s)\mathbb{E}^{\mathbb{P}}(xy) + \mathbb{E}^{\mathbb{P}}(x)\mathbb{C}\text{ov}^{\mathbb{P}}(s, y) + \mathbb{E}^{\mathbb{P}}(y)\mathbb{C}\text{ov}^{\mathbb{P}}(s, x) + \mathbb{E}^{\mathbb{P}}(\Delta s \Delta x \Delta y),
\end{aligned}$$

where $\Delta. = . - \mathbb{E}^{\mathbb{P}}(.)$. The second term can be rewritten as

$$\begin{aligned}\mathbb{E}^{\mathbb{P}}(sx)\mathbb{E}^{\mathbb{P}}(sy) &= \left(\mathbb{E}^{\mathbb{P}}(s)\mathbb{E}^{\mathbb{P}}(x) + \mathbb{C}\text{ov}^{\mathbb{P}}(s,x)\right)\left(\mathbb{E}^{\mathbb{P}}(s)\mathbb{E}^{\mathbb{P}}(y) + \mathbb{C}\text{ov}^{\mathbb{P}}(s,y)\right) \\ &= \mathbb{E}^{\mathbb{P}}(x)\mathbb{E}^{\mathbb{P}}(y) + \mathbb{E}^{\mathbb{P}}(x)\mathbb{C}\text{ov}^{\mathbb{P}}(s,y) + \mathbb{E}^{\mathbb{P}}(y)\mathbb{C}\text{ov}^{\mathbb{P}}(s,x) + \mathbb{C}\text{ov}^{\mathbb{P}}(s,x)\mathbb{C}\text{ov}^{\mathbb{P}}(s,y).\end{aligned}$$

Combining together, we obtain

$$\mathbb{C}\text{ov}^{\mathbb{S}}(x,y) = \mathbb{C}\text{ov}^{\mathbb{P}}(x,y) + \underbrace{\mathbb{E}^{\mathbb{P}}(\Delta s \Delta x \Delta y)}_{\text{third-moment term}} - \underbrace{\mathbb{C}\text{ov}^{\mathbb{P}}(s,x)\mathbb{C}\text{ov}^{\mathbb{P}}(s,y)}_{\text{second-order term}}.$$

The third-moment term $\mathbb{E}^{\mathbb{P}}(\Delta s \Delta x \Delta y) = 0$ under joint normality. The second-order terms is equal to zero in the continuous time limit where x and y are increments of Ito processes and, hence, the squared covariance term is of the order $(dt)^2$. Similarly, this second-order term is small compared to the covariance $\mathbb{C}\text{ov}^{\mathbb{P}}(x,y)$ if x and y represent changes over small time periods.

A.2 Earnings measurement consistent with I/B/E/S

To be consistent with the I/B/E/S's definition of earnings, we follow De la O et al. (2024) and Hillenbrand and McCarthy (2022) and define earnings as Compustat net income (item NIq) excluding non-I/B/E/S items, which comprise extraordinary items and discontinued operations (item XIDOq), special items (item SPIq), and non-recurring income taxes (item NRTXTq) as follows,

$$Earnings_t = NIq_t - XIDOq_t - SPIq_t - NRTXTq_t.$$

The I/B/E/S actuals and Compustat net income excluding non-I/B/E/S items track each other closely, with a correlation of 0.99 (see Figure A-2, panel A).

We treat missing values in the XIDOq, SPIq, and NRTXTq variables as zeros. That is, if none of these three variables are populated in a given firm-quarter, we do not remove anything from net income in this quarter. Similar to De La O and Myers (2021), De la O et al. (2024), and Bordalo et al. (2024a), we use quarterly updated rather than annual data. This is to match the forecasted earnings from I/B/E/S, which are available at a quarterly frequency. To rule out that our data is affected by the sampling frequency of the balance sheet data, we have compared quarterly net income, extraordinary items and discontinued operations, special items, and non-recurring income taxes with their annual counterparts (i.e., items NI, XIDO, SPI, and NRTXT, respectively). While we identify very small differences when comparing the two time series for net income, we find virtually no differences for all other items.

We then use the quarterly earnings data to construct a monthly sampled time-series of annual earnings at the firm level. To that end, at every month, we calculate annual earnings at the firm level as the sum of quarterly earnings from the most recent four quarters. Finally, following De La O and Myers (2021), the realized aggregate earnings are calculated by summing the total earnings reported by each firm and adjusting by the S&P 500 index divisor.

Figure A-1 illustrates the coverage of firm-level earnings forecasts for S&P 500 constituents. While coverage is high for 1- and 2-year-ahead forecasts, it drops sharply for horizons of 3, 4, and 5 years. Even at the 1- and 2-year horizons, however, forecasts are not available for all S&P 500 firms. To address this, we follow De La O and Myers (2021) and assume that firms with available earnings forecasts constitute a representative sample of the S&P 500. Based on this assumption, we proxy for aggregate expected S&P 500 earnings by dividing the sum of forecasted earnings for firms with available 1-year (or 2-year) forecasts by the ratio of their aggregate market capitalization to the S&P 500 index level. This yields an estimate of equity analysts' 1-year (or 2-year) ahead earnings forecasts on a per-share basis for the S&P 500. We apply the same aggregation approach to realized earnings using the Unadjusted Actuals file, thereby obtaining an estimate of reported S&P 500 earnings per share.

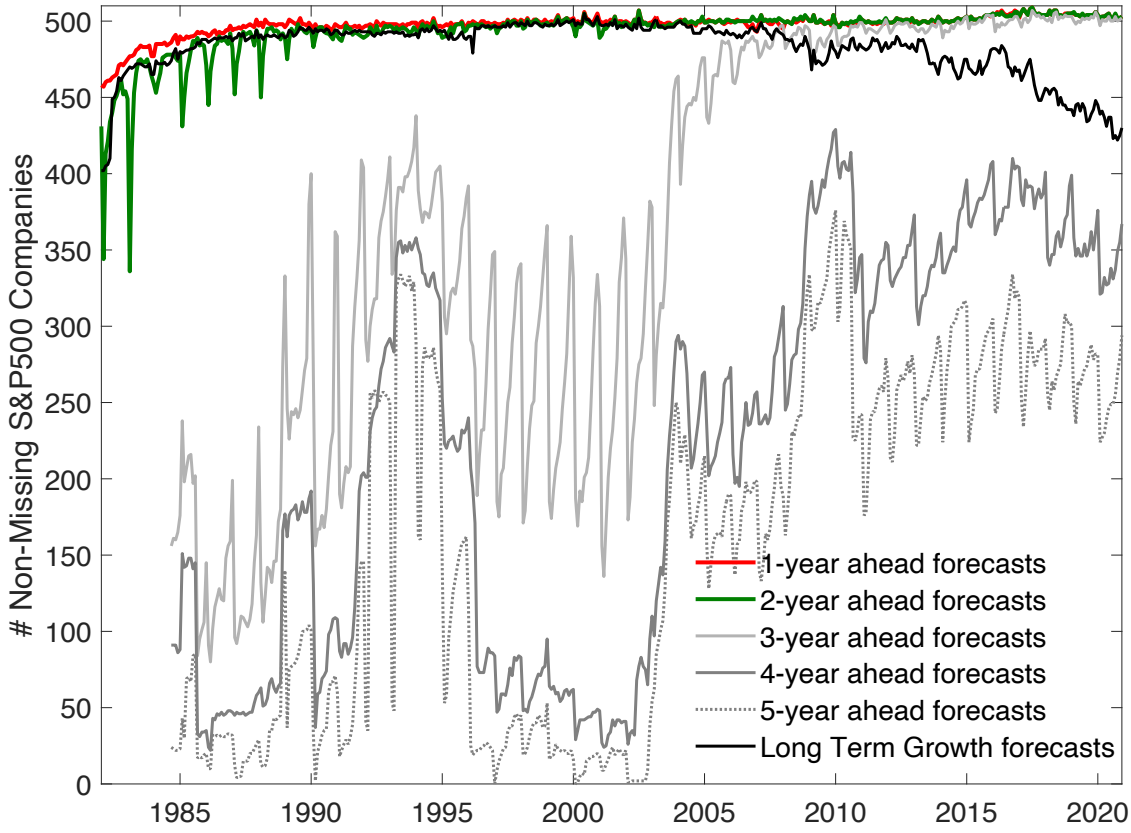

Figure A-1: **I/B/E/S Coverage**: This graph plots the number of S&P500 companies for which we have non-missing I/B/E/S 1- to 5-year and Long Term Growth forecasts over the periods 1982:M1 to 2020:M12, respectively. Data are monthly and run from January 1982 to December 2020.

A.3 Return expectations

We obtain monthly data on sell-side analysts median forecasts of dividend per share (DPS) from the US Unadjusted Summary Statistics of the Thomson Reuters I/B/E/S Estimates Database (hereafter referred to as IBES). We obtain monthly median price targets (PTG) from the IBES US Unadjusted Summary Price Targets files. This dataset covers a wide array of US stocks from March 1999. The vast majority of price target forecasts are for a twelve-month horizon. Dividend expectations from I/B/E/S are only available for a broad cross-section of firms from 2002/05, so the sample period begins in May 2002.

Dividend per share (DPS) forecasts are provided in the third week of every month for different fiscal years (FY) or fiscal quarters (QTR). This differs from PTGs, which are rolling twelve-month horizon forecasts. Therefore, we use interpolation as in De La O and Myers (2021) to obtain one-year DPS forecasts on a rolling window basis, aligning them with the PTGs.

The subjective expected return from I/B/E/S is:

$$\mathbb{E}_t^{\mathbb{S}} R^e_{i,t,t+12} = \frac{\mathbb{E}_t^{\mathbb{S}}\left[P_{t+12}\right] + \mathbb{E}_t^{\mathbb{S}}\left[DPS_{t+12}\right]}{P_{t-1}}$$

From CRSP, we obtain cumulative share adjustment factors (CFACSHR), and cumulative price adjustment factors (CFACPR). $\mathbb{E}_t^{\mathbb{S}}\left[P_{t+12}\right]$ is the median consensus one-year price target multiplied by the cumulative price adjust-

ment factor at the time the consensus forecasts are constructed; $\mathbb{E}_t^{\mathbb{S}}[DPS_{t+12}]$ is the one-year dividend per share consensus expectations multiplied by the cumulative share adjustment factor at the time the consensus forecasts are constructed; and P_{t-1} is the adjusted price at the end of month $t-1$.

A.4 Stock price variance decomposition: Robustness and additional discussion

Table A-1 reports the four components of the decomposition:

$$1 = \overbrace{\underbrace{\frac{\mathbb{C}\text{ov}[x_t, \mathcal{F}_{d,t}^{\mathbb{S}}]}{\mathbb{V}\text{ar}[x_t]}}_{(3)} - \frac{\mathbb{C}\text{ov}[x_t, \mathcal{B}_t^{\mathbb{S}-\mathbb{P}}]}{\mathbb{V}\text{ar}[x_t]}}^{(1)} + \overbrace{\underbrace{\frac{\mathbb{C}\text{ov}[x_t, -\mathcal{F}_{r,t}^{\mathbb{S}}]}{\mathbb{V}\text{ar}[x_t]}}_{(4)} + \underbrace{\frac{\mathbb{C}\text{ov}[x_t, \mathcal{B}_t^{\mathbb{S}-\mathbb{P}}]}{\mathbb{V}\text{ar}[x_t]}}_{(5)}}^{(2)} \tag{A-1}$$

for alternative choices of the valuation ratio x_t. The variable PD refers to the price-dividend ratio used in our baseline VAR specification. The Shiller CAPE corresponds to the ten-year cyclically adjusted price-to-earnings ratio, sourced from Robert Shillers website.[31]

Table A-1: **Variance Decompositions.** This table reports the four components of the decomposition (A-1) for alternative choices of the valuation ratio x_t. PD corresponds to the ratio of the S&P500 index to dividends reported by Amit Goyal on his website. PE-STREET corresponds to the ratio of the S&P500 index scaled by the average of the past three years I/B/E/S reported actuals. Shiller CAPE corresponds to the ten year cyclically-adjusted price-to-earnings ratio sourced from Shillers website. PE-GAAP corresponds to the ratio of the S&P500 index scaled by last years reported GAAP earnings (i.e., price-to-GAAP earnings ratio). PE-GAAP (excluding non-IBES items) is calculated using GAAP earnings adjusted to remove items not captured by I/B/E/S actuals.

	(1)	(2)	(3)	(4)	(5)
PD	0.02	0.98	0.26	0.74	0.24
	(0.48)	(23.38)	(3.83)	(10.94)	(2.19)
PE Street	0.00	1.00	0.26	0.74	0.26
	(0.00)	(15.13)	(2.90)	(8.23)	(2.06)
PE Shiller CAPE	0.11	0.89	0.33	0.67	0.22
	(2.04)	(16.47)	(5.80)	(11.70)	(2.09)
PE GAAP (excluding non-IBES items)	-0.300	1.30	0.28	0.72	0.58
	(-4.20)	(18.15)	(2.22)	(5.68)	(4.03)
PE GAAP	0.45	0.55	0.69	0.31	0.24
	(2.44)	(2.98)	(4.77)	(2.14)	(2.62)

The first row presents our benchmark results using $x = pd$. We find that, even after adjusting for biases, variation in discount rates remains the dominant driver of stock market volatility, accounting for 74% of the variance in the price-dividend ratio under investors beliefs. Similar results hold when we use either the Shiller CAPE or a price-to-earnings ratio constructed by scaling prices with smoothed "STREET earnings,"[32] with discount rate

[31] http://www.econ.yale.edu/~shiller/data.htm

[32] Following Hillenbrand and McCarthy (2022), we define smoothed STREET earnings as a three-year moving average of I/B/E/S-reported actuals, providing a more timely proxy for valuation ratios than the Shiller CAPE.

variation explaining between 67% and 74% of the variance. Importantly, the fact that our findings hold even when using the street earnings-based P/E ratiowhich is less persistent than the PD or CAPE ratiossuggests that our conclusions are not driven by long-term trends in the data.

Overall, our results are robust across different valuation measures, including the Shiller CAPE, the price-to-earnings ratio based on "Street" earnings (PE-Street), and the PE-GAAP excluding transitory items captured in GAAP earnings but not in I/B/E/S actuals.

However, results change substantially when the price-to-earnings ratio is constructed using unadjusted GAAP earnings. In this case, investors' beliefs about cash-flow growth account for 69% of the variance in the valuation ratio, while discount rate variation explains only 31%. Notably, the contribution of belief-based bias to valuation ratio volatility remains stable across all valuation measures.

The shift in the term $\frac{\mathbb{C}\text{ov}[x_t, \mathcal{F}^{\mathbb{S}}_{d,t}]}{\mathbb{V}\text{ar}[x_t]}$ in the decomposition stems from differences in the earnings measure, E_t, used to compute the price-to-earnings ratio.

To illustrate this, the top panel of Figure A-2 plots alternative earnings measures. Earnings reported by equity analysts in the I/B/E/S system (Street earnings) closely track Compustat net income excluding non-I/B/E/S items, which we use in our baseline measure. In contrast, Compustat net income excluding extraordinary items, calculated under Generally Accepted Accounting Principles (GAAP earnings), is significantly more volatile and dropped sharply during the financial crisis. The discrepancy between these earnings measures is large but well understood, largely driven by "special items"—non-recurring charges and one-time impairments (Bradshaw and Sloan, 2002).[33]

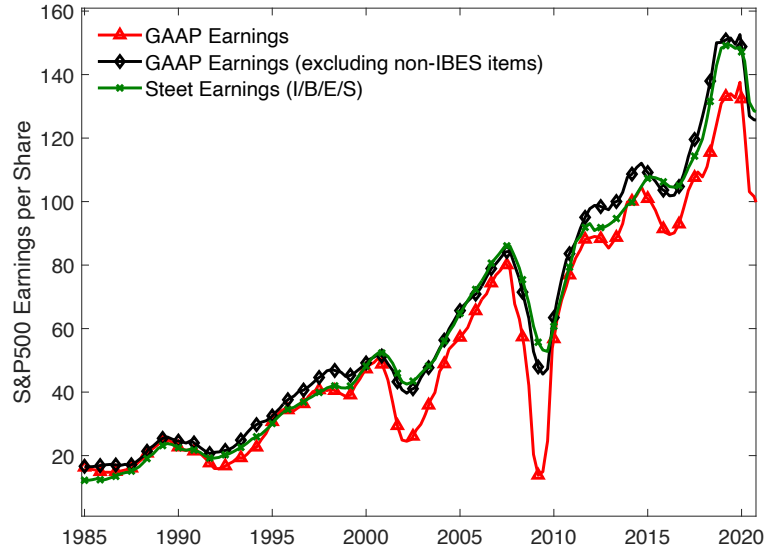

This distinction matters for our analysis. The bottom panel of Figure A-2 provides a comparison of different valuation ratios for the S&P 500. The price-to-GAAP earnings ratio spikes—rather than declines—during the financial crisis due to the sharp collapse in GAAP earnings. This drop mechanically inflates forecasted earnings growth, as analysts exclude the earnings decline driven by special items from their forecasts. As a result, there is a mechanical comovement between the price-to-earnings ratio and one-year-ahead earnings growth forecasts.[34] This strong comovement is substantially reduced when STREET earnings are used as the denominator.

The price-to-GAAP earnings ratio shoots up (rather than falling) in the financial crisis, because the drop in GAAP earnings is so large. At the same time, the large drop in earnings mechanically leads to a dramatic increase in forecasted earnings growth, because analyst exclude the drop in earnings due to special items from their forecasts, leading to a mechanical comovement of price-to-earnings ratio and forecasts of (one-year) earnings growth. The strong co-movement arises for both realized and forecasted earnings growth when using GAAP earnings decreases substantially when using STREET earnings as the scaling factor.

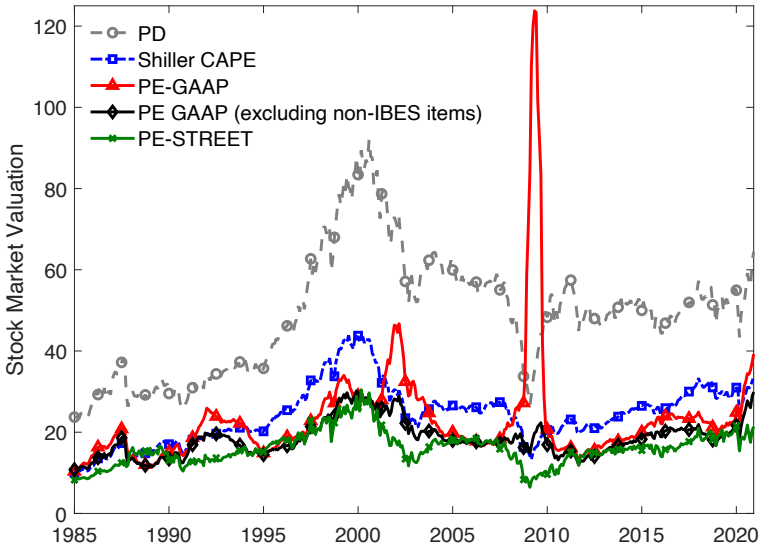

We therefore base our conclusions in this robustness section on valuation ratios constructed with STREET earnings for two main reasons. First, equity analysts issue forecasts of STREET earnings, making it more appropriate to use them as the scaling factor. Second, our interest lies in explaining asset pricesthe numerator of the ratiorather than dissecting the accounting properties of the denominator. For these reasons, we prefer valuation ratios that more directly reflect price dynamics.

[33] According to Bradshaw and Sloan (2002), many of the charges excluded from Street earnings correspond to discontinued operations, extraordinary and non-recurring items, and the special items line item in Compustat. These special items typically include restructuring charges, asset impairments, merger and acquisition expenses, and other significant non-recurring costs.

[34] See also Nagel (2024).

A S&P500 Earnings Measures

B S&P500 Price Ratios

Figure A-2: **Comparison of S&P500 earning measures and related price ratio** : Panel A plots the normalized S&P500 earnings per share for (1) GAAP earnings: net income excluding extraordinary items, calculated under Generally Accepted Accounting Principles; (2) Street Earnings, which refer to actual earnings reported by I/B/E/S (Unadjusted Actuals files), (3) GAAP Earnings (excluding non-IBES items) is Compustat net income excluding discontinued, special and extraordinary items and non-recurring income taxes. Panel B plots price ratios of S&P500 using different type of earnings. PE-STREET Earnings corresponds to the ratio of the S&P500 index scaled by the average of the past three years I/B/E/S reported actuals at the S&P500 level. PE-GAAP corresponds to the ratio of the S&P500 index scaled by last years reported GAAP earnings at the S&P500 level. Shiller CAPE corresponds to the cyclically-adjusted price earnings ratio taken directly from Shillers website. PD corresponds to the ratio of the S&P500 index to dividends reported by Amit Goyal on his website. Data are monthly and run from January 1985 to December 2020.

A.5 Additional tables and figures

Table A-2: **VAR model with short-term earnings forecasts only.** Panel A of this table reports the coefficients on the explanatory variables in the VAR model. Each row corresponds to a different equation of the model. The variables include the market excess return (r_t^e), the revisions in analysts' forecast of market earnings growth ($\varepsilon_{d,t}^{\mathbb{S}}$), analysts' forecast of market earnings growth ($\mathcal{F}_{d,t}^{\mathbb{S}}$), the market price-to-dividend ratio (pd_t), and the yield spread between short-term and long-term government bonds (ty_t). Ordinary least squares t-statistics are reported in parentheses below the coefficients. The last column reports the R^2. Panel B reports the fraction of the variation in excess market return and in the revisions in analysts' forecast of market earnings growth at H-month horizon explained by the VAR forecast computed from the estimated VAR model. Results use analysts' forecast of short-term earnings growth and an estimate of growth rate persistence as specified in equation (18). Data are monthly from January 1982 through December 2020.

Table A-3: **ICAPM with EPS that include extraordinary items.** This table reports the results of the cross-sectional regression of mean excess portfolio returns on portfolio betas estimated in the first-pass univariate regressions. The model is estimated using 51 portfolios: 20 risk portfolios, 10 Fama-French book-to-market ranked portfolios, 10 Fama-French size ranked portfolios, 10 momentum ranked portfolios, and the market portfolio. The table reports the estimates of the constant term and the factor risk premia for cash-flow news ($\varepsilon^{\mathbb{P}}_{d,t}$), discount-rate news ($\varepsilon^{\mathbb{P}}_{r,t}$), and bias shock ($\varepsilon_{\mathcal{B},t}$). t-statistics based on the GMM-VARHAC standard errors for these estimates are reported in the parentheses. The table also reports the R^2 of the cross-sectional regression and its p-value under the null that $R^2 = 1$. Finally, the table reports the statistic and the associated p-value of the chi-squared test of the null hypothesis that all pricing errors are jointly zero. Columns (1)-(4) report the results in which we use the analysts' forecast of both short-term and long-term earnings growth as specified in equation (17). Columns (5)-(8) report the results in which we use analysts' forecast of short-term earnings growth and an estimate of growth rate persistence as specified in equation (18). Data are monthly from January 1982 through December 2020.

Table A-4: **Comparing IBES vs. CRSP-Compustat coverage.** This table shows the average coverage provided for each of testing portfolios by IBES relative to CRSP-Compustat between 2002 and 2020. Our testing portfolios contains FF single sorted portfolios by market capitalization (ME), book-to-market (BM), momentum (MOM) and 20 risk-sorted portfolios, respectively. The coverage is presented in terms of the availability of subjective expected returns at the portfolio level. Panel A provides the average coverage as a percentage of the number of stocks, and Panel B provides the average coverage as a percentage of market capitalization (ME). All values are rounded to one decimal place.

Panel A Coverage ME (%)										
Small ME	63.74	Lo BM	99.42	Lo MOM	97.04		Lo VS Beta	Hi VS Beta	Lo TY Beta	Hi TY Beta
ME 2	86.50	BM 2	99.53	MOM 2	98.33	Lo Mkt Beta	98.69	98.99	98.70	98.86
ME 3	92.49	BM 3	99.57	MOM 3	98.06	Mkt Beta2	98.58	99.15	98.98	99.03
ME 4	95.00	BM 4	99.31	MOM 4	98.54	Mkt Beta3	99.00	99.35	99.12	99.30
ME 5	96.51	BM 5	98.94	MOM 5	98.84	Mkt Beta4	98.94	99.31	98.85	99.28
ME 6	96.98	BM 6	98.86	MOM 6	98.88	Hi Mkt Beta	98.48	98.73	98.45	98.71
ME 7	97.45	BM 7	98.18	MOM 7	99.12					
ME 8	98.54	BM 8	98.09	MOM 8	99.20					
ME 9	99.69	BM 9	96.52	MOM 9	98.98					
Big ME	99.72	Hi BM	93.11	Hi MOM	98.61					
Panel B Coverage # of Stocks (%)

Figure A-3: **Shocks**: This figure plots the ($\varepsilon^{\mathbb{P}}_{d,t}$), discount-rate news ($\varepsilon^{\mathbb{P}}_{r,t}$), and belief shocks ($\mathbf{e}_2^{\intercal}\mathbf{u}_t$) smoothed with a trailing exponentially-weighted moving average. The decay parameter is set to 0.08 and, given the series x_t the smoothed series ma_t are generated as $ma_t = 0.08 \times x_t + (1-0.08) \times ma_{t-1}$. Shaded areas correspond to NBER recessions. Results use the analysts' forecast of both short-term and long-term earnings growth as specified in equation (17). Data are monthly and run from January 1982 to December 2020.

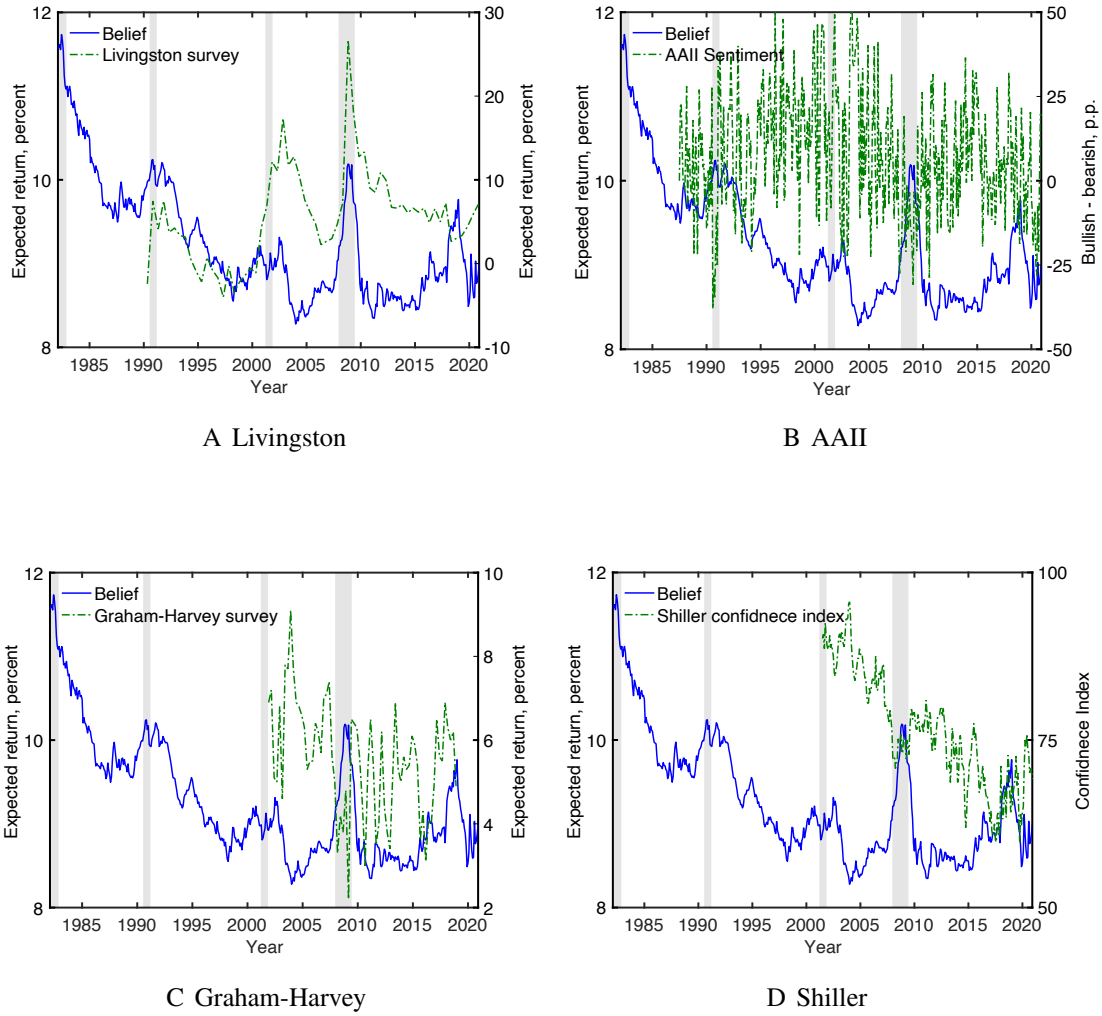

Figure A-4: **VAR beliefs vs survey data**: This figure plots the belief about long-term market returns $\mathcal{F}^{\mathbb{S}}_{r,t}$ obtained as the VAR forecast adjusted for the bias using equation (5) alongside, respectively, the expected market return implied by the Livingston survey from Adam et al. (2021) (Panel A), the difference between the fractions of bullish and bearish investors from the AAII sentiment survey (Panel B), the expected market return from the Graham-Harvey survey of CFOs (Panel C), and the Shiller one-year individual investor stock market confidence index. Results use the analysts' forecast of both short-term and long-term earnings growth as specified in equation (17).
