Matching People to Properties: A Matching Function for the Housing Market*

March 2026

Abstract

Housing markets are subject to search frictions. The matching function is a widely used tool in macroeconomics to summarize labour-market search frictions and has been estimated in an extensive literature. Limited data on home-buyers has precluded estimation of housing-market matching functions. This paper fills that gap using a novel dataset identifying buyers and their search behaviour in viewing properties. An event study based on the staggered removal of restrictions on housing purchases provides causal estimates of the elasticity with respect to buyers for a constant-returns-to-scale Cobb-Douglas matching function, which is found to be around 0.5.

*We thank Qian Zhang and Xiangyu Zhou for excellent research assistance, and Ting Chen for sharing information on Chinese housing-market regulations. We thank Russell Cooper, Maarten De Ridder, Essi Eerola, Hanming Fang, Eric French, David Genesove, Jim Hamilton, Leo Kaas, Barbara Petrongolo, Chris Pissarides, Valerie Ramey, Wenxuan Wang, Weilong Zhang, and Shu Yang for helpful discussions. 1 Introduction

Search frictions are central to markets for labour, goods, money, marriage, credit, and housing where buyers and sellers do not match instantaneously. The concept of a matching function is a powerful tool to capture the complexity of the search process on both sides of the market in a tractable way. The matching function describes the number of transactions between buyers and sellers with positive total surplus that are realized in a period of time given the search technology, independent of how the surplus is divided. As formalized by Pissarides (1979), it acts as a production function for matches conditional on the numbers of buyers and sellers, analogous to how factor inputs are combined to produce output. This key innovation established search models as the canonical framework for studying the labour market in macroeconomics to address issues such as unemployment, business cycles, and policy.[1] The objective of this paper is to provide empirical evidence on the housing-market matching function.

The housing market shares the heterogeneity of buyers and sellers and imperfect information seen in the labour market (Clark, 1982), and since the seminal work of Wheaton (1990), a growing literature has adopted the search framework to study interactions between housing markets and macroeconomics. A matching function between home-buyers and properties for sale determines the number and speed of transactions.[2] This is important because transactions represent gains from trade that reduce housing mismatch, and the speed with which they occur affects the duration of mismatch. Typically, researchers assume a Cobb-Douglas, constant-returns matching function, often imposing an elasticity of 0.5 or calibrating indirectly. However, empirical evidence on the housing-market matching function remains scarce due to the lack of direct data on buyers. Genesove and Han (2012) infer the ratio of buyers to sellers (market tightness) indirectly from surveys of successful buyers and sellers, while recent work using land registry data or online platforms captures only a partial component of buyer activity.[3]

[1] An influential survey by Petrongolo and Pissarides (2001) of more than 40 papers that investigated empirically the functional form or parameters of the labour-market matching function concluded that it has a Cobb-Douglas functional form, constant returns to scale, and an elasticity with respect to vacancies (buyers) of between 0.3 and 0.5.

[2] Recent papers that use a matching function for the housing market include Head et al. (2014), Burnside et al. (2016), Guren (2018), Gabrovski and Ortego-Marti (2019), Garriga and Hedlund (2020), Guren and McQuade (2020), Piazzesi et al. (2020), Han et al. (2025), and Kaas et al. (2026).

[3] Grindaker et al. (2025) use Norwegian Land Registry data to infer changes in tightness using the fraction of movers who buy first. Examples from online platforms include the use of clicks on property listings in van Dijk and Francke (2018) for the Netherlands, email alerts in Piazzesi et al. (2020) for

This paper presents a novel approach to estimating the housing-market matching function. First, it exploits a unique dataset that directly identifies buyers and their search effort in a large housing market, combining information from an online platform together with offline viewing data. Second, it uses an event study that leverages the staggered removal over time of legal restrictions on housing purchases across districts in two large provinces of China. The results support an elasticity of matches with respect to home-buyers of approximately 0.5 for a Cobb-Douglas matching function with constant returns to scale.

The data used in this paper come from the largest real-estate transaction platform in China, which integrates both online listings and offline viewings. The platform's online app is similar to Zillow in the US and Rightmove in the UK. A key difference is that all offline viewings are recorded on the platform's integrated system, and offline viewings are linked to unique buyer and listing IDs. Therefore, we can focus on users who actually view properties and engage as active buyers in the housing market, as opposed to users who merely browse online.

Accounting for search effort is an important challenge when estimating matching functions. The data allow us to construct a measure of effective buyers based on the number of viewings made by active buyers in a given period of time. The output of the matching function is the number of transactions, and data on this are also available based on the date a contract is signed.[4] Hence, together with the stock of listings, we have data on all the variables appearing in the matching function.

The data are from 15 major cities in two provinces of China with a total population of over 100 million people. Listings are grouped geographically by districts, which are sub-regions of cities. The sample used in our analysis includes 116 districts, with a median population of 785,000 and a median area of 1,440 km^2. Since we can show that buyers' search radius is largely confined to a single district, we aggregate listings, effective buyers, and transactions within districts. Our interest is to estimate an aggregate matching function, so we do not estimate separate matching functions for different types of housing, such as large or small apartments within a district. A more fundamental reason is that housing has multiple attributes that are substitutable for buyers, for example, a small apartment in a certain neigbourhood could be as attractive

the San Francisco Bay Area, clicks on the contact button in Kaas et al. (2026) for Germany, and IP addresses in Badarinza et al. (2024) for the UK.

[4]It is well known that there can be a substantial difference between the contract date and the closing date when ownership of the property is transferred (Anenberg and Laufer, 2017).

as a large apartment in another neighbourhood. This means it is not appropriate to estimate independent matching functions for different housing-market segments within a district.[5] The time period covered by the data is November 2021 to December 2024, and variables are aggregated within months.

First, following earlier literature, we estimate the functional form of the matching function using OLS panel regressions that include both district and time fixed effects. The fixed effects remove common macroeconomic trends and fluctuations and control for heterogeneity across districts. This is to address concerns about unobserved variation in matching efficiency that might be correlated with the numbers of buyers or sellers, but we discuss the limitations of this approach. Starting with a trans-log specification, we show that second-order terms are statistically insignificant, failing to reject a Cobb-Douglas (log linear) functional form. We also do not reject the hypothesis that the matching function has constant returns to scale (CRS). Therefore, we proceed by assuming a CRS Cobb-Douglas matching function.

Our main empirical contribution leverages changes in legal restrictions on buying properties in China that vary at the district level to conduct an event study. The Chinese government has long imposed tight controls on the housing market. Traditionally, there are restrictions on who can purchase property where, and how many properties they can own. While such restrictions have been in place for a long time, recent years have seen changes in policy that led to several of these restrictions being lifted across China. Importantly, while the initial trigger for this change was a central announcement to stimulate housing demand at national level, the timing of the legislative lifting of restrictions varied across cities and districts. We provide evidence that the district-level policy timings are not correlated with local market conditions. Instead, the pattern of the staggered roll-out is consistent with China's broader practice of policy experimentation, in which reforms are first introduced in lower-stakes areas before wider adoption (Wang and Yang, 2025). This offers a unique opportunity to utilize the effects of lifting housing-market restrictions for estimating the matching function.

We then use a staggered differences-in-differences (DID) research design in which the treatment is the removal of housing purchase restrictions at the district level. Since all districts that had restrictions eventually removed them, but the timing of removal

[5] A matching function is an essential ingredient for any equilibrium search model, including both random-search and directed-search approaches. Although the latter allows for different sub-markets, the same matching function is typically assumed for all sub-markets.

varied across districts, this is a staggered and absorbing treatment. The control group consists of districts that have not yet removed their restrictions at a given point in time, with districts that never had restrictions being excluded. This approach does not require assuming that districts without restrictions are comparable to those with them. Instead, identification comes from variation in the timing of removal among districts that all eventually remove their restrictions.

The event studies show an absence of pre-trends, supporting the key identification assumption of parallel trends in absence of the treatment. We find that from around one to one-and-half years after the lifting of restrictions, both buyers and transactions increase significantly. We find no significant effect on inventories, however. We then exploit the heterogeneous treatment effects by cohort and time to obtain an estimated elasticity with respect to buyers of 0.499 for a CRS Cobb-Douglas matching function. This is around 30 percent larger than the point estimate obtained from an OLS panel regression.

The outline of the paper is as follows. After discussing related literature below, we briefly review the concept of a matching function and the importance of incorporating search effort in section 2. Section 3 describes the data and defines the key variables, and section 4 presents results from the OLS panel regression. Section 5 describes the event study and reports the causal estimates of the matching function elasticity. Section 6 concludes.

Related literature High quality data on home-buyers are scarce. A key advantage of our paper is the direct measurement of buyers and their search effort that comes from the data on offline viewings.

We are aware of only three papers that aim to estimate a matching function for the housing market.[6] The most well known is Genesove and Han (2012), which uses the U.S. National Association of Realtors Survey of Buyers and Sellers who have successfully completed a transaction in 11 of the years between 1987 to 2008. From data on times taken to sell and buy and assuming a CRS matching technology, they infer the market tightness. Together with data on the number of homes visited, they estimate the elasticity of the contact (viewing) hazard with respect to market tightness. There are

[6]There are two other papers that also estimate the elasticity of a CRS matching function as part of research investigating the dynamics and spatial dispersion of house prices. Grindaker et al. (2025) infer changes in market tightness using the share of movers who buy first in Norway and estimate the elasticity of time-to-sell with respect to tightness. Kaas et al. (2026) infer the number of buyers using data on contacts (clicking on the 'contact button') from an online platform in Germany.

two advantages of our data. First, we can directly identify buyers and their search effort. Second, our data includes buyers and sellers during their search process, not only those who successfully completed a transaction, a retrospective sample.[7]

Since the rise of online real-estate platforms in the late 1990s, there is now more information available about buyers to facilitate estimating a matching function. Vidal (2022) identifies buyers from users of an online valuation tool in France. He estimates a Cobb-Douglas matching function and finds that CRS is rejected. However, that study has a small coverage of buyers actively searching for a property because the identified stock of buyers is seven times smaller than the flow of transactions on average. Compared to Genesove and Han (2012) and Vidal (2022), we have an event study that gives an exogenous source of variation in buyers.

A study with a more comprehensive coverage of buyers is Badarinza et al. (2024), which uses data from the largest online platform in the UK together with Land Registry data. In their paper, they use IP addresses as a proxy for unique users to estimate the number of buyers, and the numbers of online clicks to browse properties and clicks to contact agents as proxies for search effort. That paper estimates a CRS Cobb-Douglas matching function using a natural experiment based on the 2022 UK 'mini budget', which has a significant effect on market tightness. However, it has no significant effect on transactions. Our staggered roll-back of housing purchase restrictions gives statistically significant effects on both buyers and transactions, which we use to estimate the matching-function elasticity.

2 Framework

There are many factors that determine the number of properties for sale and the number of buyers, such as prices, interest rates, and the state of the economy. In a frictionless market, transactions coincide with demand and supply in equilibrium. However, with frictions arising from imperfect information and heterogeneity on both sides of the housing market, even once the numbers of properties and buyers are determined, matching is not instantaneous, resulting in the coexistence of unmatched sellers and buyers. A matching function serves as a powerful tool to summarize the complex pro-

[7] Using micro data from Los Angeles, Clark and Smith (1982) compare households during the search process (a longitudinal sample) with those who have already bought (a retrospective sample). They find that on average, those in the longitudinal sample visit 50% more houses and search for three times longer, and many of them withdraw without buying.

cess of matching, allowing researchers to focus on the implications of search frictions rather than on their underlying causes.

The matching function describes the number of transactions with positive total surplus that are realized in a period of time given the search technology and the numbers of buyers and sellers searching.[8] Formally, the flow of transactions Q in a period of time is a function of the stock of properties for sale U and demand D coming from the stock of buyers searching for properties:

$$Q = m(D, U)\,. \tag{1}$$

If a time period is one month, the function specifies the number of successful transactions in that month given demand and supply during the month. What the matching function captures is not the number of transactions that will *ultimately* result from D and U, but the speed at which buyers and sellers can find a successful match given search frictions. Even if each buyer and seller ultimately finds a match with certainty, the matching function is important in describing how changes in D and U affect transaction speed.

In specifying a matching function, Pissarides (2000) emphasizes that transaction speed depends on search effort, not just the numbers of buyers and sellers.[9] In the context of the housing market where buyers typically take the initiative, it is crucial to consider buyers' search effort. If B is the raw number of buyers and the average search effort per buyer is e, the effective buyer input into the matching function is

$$D = eB\,, \tag{2}$$

which represents demand from 'effective' buyers.[10] The variable B can be thought of as capturing the 'extensive margin' and e the 'intensive margin'.

In the housing literature, there is plenty of data on properties for sale, especially after the rise of online property listings.[11] But data on buyers' demand are more scarce,

[8] This does not depend on knowing prices, which govern the division of the surplus. Prices might be of interest in their own right as an outcome of matching and bargaining, but that is not the focus of this paper.

[9] For the labour market, recent work, e.g. Davis et al. (2013), highlights the importance of recruiting intensity (buyer's search effort) when specifying a matching function.

[10] See Gavazza et al. (2018) for a similar specification for the labour market where they define effective vacancies (buyer) as the input into the matching function.

[11] The first website offering online access to U.S. Multiple Listing Service properties began in 1995 (HomeSeeker.com).

unlike in labour-market matching-function estimation where researchers have access to both data on unemployment and vacancies explicitly. Online platforms provide information on buyers who are searching, such as the number of clicks, the number of people who subscribe to email alerts, IP address and contacts (van Dijk and Francke, 2018; Piazzesi et al., 2020; Badarinza et al., 2024; Kaas et al., 2026).

Our data provide a measure of buyers undertaking more serious search effort, namely viewing properties. This is a better measure given that significant time is required to make a viewing, whereas clicks, signing up to email alerts, etc., require almost no time or effort and can be done by those with no intention of buying, such as those browsing for curiosity, or even sellers themselves. We measure raw buyers B as the number of people who view at least one property in a period of time. Proxying search effort e by the number of viewings made per buyer, our overall measure of effective buyers D is the total number of viewings undertaken by all buyers.

Researchers using the matching function equation (1) would like to know the functional form, degree of returns to scale, and elasticities of transactions with respect to buyers and sellers. One fundamental challenge to identification is that observed inputs (buyers and properties) into the matching function are likely correlated with the unobserved matching efficiency (analogy to production efficiency for production function).[12] This resembles the challenge that the literature has faced when estimating production functions (see Ackerberg et al., 2015, for a review) and labour-market matching functions (see Yashiv, 2000, for an early example). Addressing this concern is important because, as demonstrated by Borowczyk-Martins et al. (2013), one can provide theoretical arguments why efficiency and the number of buyers and sellers in a market should be correlated.

As first attempt, we followed the literature by exploring whether imposing a Markov structure on match efficiency enables us to use GMM estimators (Arellano and Bond, 1991; Blundell and Bond, 2000) to obtain identified results on the parameters of interest. However, due to a high degree of persistence in properties listed for sale, there are no instruments that are sufficiently strong to yield reliable empirical results on functional form and degree of returns to scale using either difference GMM or system GMM.

[12] Lange and Papageorgiou (2020) raise a different concern that when match efficiency responds to the outcome of the matching process, no instrument can simultaneously impact market tightness and be exogenous. However, most applications of a matching function would be concerned with the total effect on the output of transactions from given inputs, including the indirect effect on match efficiency.

Therefore, we turn to what has been the most common approach in the housing-search and earlier labour matching-function literatures of using panel estimation. These OLS regressions do not reject a constant-returns-to-scale Cobb-Douglas matching function. We acknowledge that the OLS estimation with fixed effects may still suffer from potential omitted variable bias. We proceed by following the housing search literature by assuming the matching function takes a CRS Cobb-Douglas form.

Our key innovation is to use an event study to obtain exogenous shifts in buyer demand to identify and estimate the elasticity of the matching function. This elasticity parameter capture the elasticity of transaction speed (the inverse of time taken to sell) with respect to changes in demand relative to the inventory of listed properties for sale. In a range of applications (Head et al., 2014; Gabrovski and Ortego-Marti, 2019; Guren and McQuade, 2020; Piazzesi et al., 2020; Han et al., 2025), one would like to know the response of housing-market liquidity as measured by transaction speed when demand increases, for example, due to changes in macroeconomic conditions such as mortgage rates or entry of new buyers, or as supply increases, for example, due to changes in new construction or zoning.

3 Data and key variables

Data source We use data from the largest real estate transaction platform in China. The platform integrates an online listing app with a large offline agent network, so all stages of the search process run through a single system. This is a unique feature that is usually missing in housing data. In markets like the US or UK, apps such as Zillow or Rightmove only record online visits. Viewings are organized by agents offline and do not enter the platform's database, which makes it difficult to measure buyers' search efforts. Our setting is different because the platform requires agents to record all viewings in real time, and these records are stored in the platform's database.

This feature enables us to fill an important gap in the literature. We observe offline viewings and can link each viewing to a unique user ID, which allows us to track both who is searching and how intensively they search. These advantages allow us to improve the measurement of buyers in the literature, which is particularly important for estimating a matching function in the housing market.

The platform mainly lists second-hand homes and therefore our data include only

those.[13] Our data include 15 major cities in two Chinese provinces: Jiangsu and Shandong. These cities are the most populous regions in the two provinces, covering about 111 million people. Each city includes several urban, suburban and rural districts. We analyze data by district and month from November 2021 to December 2024. This time period does not overlap with COVID lockdown in the cities of our analysis.[14]

Figure A.1 shows the geographical coverage of our data. Figure A.2 presents the distribution of district-level population and area. The median population of districts is about 830,000, and the median area about 930 square kilometers.

Definition of a housing market and key variables A matching function captures how quickly buyers and sellers can successfully match. While buyers and sellers may remain searching for several months, the matching function itself can be estimated with higher frequency data. We use one month as our time period because higher frequencies would result in a series for transactions with zeroes. It is important that properties transacted in a monthly period result from viewings made by their buyers within the same month. This is confirmed by Figure A.3 which shows that almost all transactions occur within 30 days of a property being viewed by its eventual buyer, and the calendar month of the eventual buyer's viewing mostly coincides with the calendar month in which the transaction is recorded.[15]

Our data also inform how we define a housing market in the spatial dimension. Across space, we define a market as a district, since Figure A.4 shows that most buyers make viewings in only one district, using micro data on all viewings in 2024 from the city of Nanjing. We therefore describe a housing market by a district-year-month, indexed by i and t.

For each (i, t), we have aggregate data on transactions Q_{it}, inventory U_{it}, and effective buyers D_{it}. Transactions Q_{it} denotes total sales agreed (contract exchanged) during the month. Inventory U_{it} is any listing that shows up on any day in a given month.[16] Effective buyers D_{it} incorporates the number of active buyers B_{it} and the

[13] New builts are often marketed and sold directly by the developers, not through a transaction platform. Therefore, our data do not include unoccupied newly built property developments in China, which are frequently referred to as 'ghost towns'.

[14] See a summary of COVID lockdown policies in Chinese cities: https://en.wikipedia.org/wiki/COVID-19_lockdown_in_China.

[15] In the empirical analysis, we verify robustness by re-estimating the matching function using quarterly aggregated data.

[16] Agents visit and verify every listing that goes live on the app. Listings that cannot be verified cannot be listed.

average search effort e_{it} as seen in equation (2). We measure number of active buyers B_{it} as the number of user IDs with at least one viewing in a given month and average search effort e_{it} as viewings per active buyer, thus effective buyer D_{it} is the total number of viewings done during a given month.[17] Our measures of buyers and properties are not based on a snapshot on any particular day of the month and thus avoid temporal aggregation bias.

Transactions Q_{it} represent an outflow from the stock of properties for sale U_{it}. The dynamics of the stock of properties on the market is linked to this outflow and other flows through a stock-flow accounting identity

$$U_{i,t+1} - U_{it} = N_{i,t+1} - Q_{it} - W_{it}\,, \tag{3}$$

where N_{it} denotes the inflow of newly listed properties during month t, and W_{it} is outflows of properties for any reason other than being sold ('withdrawals'). In the U.S., around half of properties are unsold at the point of delisting (Anenberg and Laufer, 2017). For the purposes of estimating the matching function, new listings N_{it} and withdrawals are a source of variation in the stock of properties available for sale, which might vary for many reasons.

Our data provide direct measures of all variables appearing in equation (3), including N_{it} and W_{it}. New listings N_{it} are defined as those appearing for the first time in month t. Withdrawals W_{it} are properties delisted in month t for any reason other than a sale. We check whether the identity holds in the data below.

Analysis sample and summary statistics For our main analysis sample, we impose a few restrictions. First, we exclude observations where the housing platform was nearly not present or likely just entered the local market, including observations where no inventory, viewing or transaction is recorded, and observations at the bottom 5 percentile of the ratio of inventory to population. Second, we calculate for each observation to what degree the observed data violates the stock-flow accounting given by Equation (3). The violation of this identity is given by a non-zero value when subtracting the right-hand side from the left-hand side of this equation. We normalize this error by $U_{i,t+1}$ and exclude observations at the top and bottom 5 percentile. Figure A.7 visualizes the error to the stock-flow identity before and after we apply all

[17] Agents rarely decline viewing requests. If an agent is unavailable, they will arrange for a colleague in the same office to conduct the viewing on their behalf.

of the previously described restrictions. As can be seen from the figure, imposing the described restrictions leads to the sample of analysis which is much more compliant with the stock-flow accounting identity than before our filtering.

Our main analysis sample includes 116 districts from November 2021 to December 2024. Table B.1 presents the summary statistics.

4 Baseline OLS estimation

We consider a log-linear (Cobb-Douglas) functional form in estimating the following equation:

$$\log Q_{it} = \eta_d \log D_{it} + \eta_u \log U_{it} \ + \mu_i + \zeta_t + \epsilon_{it} \,. \tag{4}$$

where the parameters η_d and η_u are the constant elasticities of transactions Q_{it} with respect to buyers searching D_{it} and inventory U_{it}. μ_i is the district fixed effect, ζ_t the time fixed effect, and ϵ_{it} the error term. The econometric challenge in estimating equation (4) is that a shift variable in the error term that captures the efficiency of matching, Z_{it}, is not directly observed. Here we assume that, once time and district fixed effects remove changes in Z_{it} that are common to all districts and differences across districts that are common over time, the remaining variation in Z_{it} is uncorrelated with D_{it} and U_{it}.

In Table 1, we start by comparing two functional forms: column (1) uses a more general translog functional form and column (2) uses a Cobb-Douglas functional form.[18] The results show that the second-order terms are all statistically insignificant in column (1), supporting a log-linear functional form. We therefore assume a Cobb-Douglas matching function in the remainder of the paper.

An important characteristic of a matching function is the degree of returns to scale, which is measured by the sum of the coefficients η_d and η_u. In column (2), we also test whether $\eta_d + \eta_u = 1$. The point estimate of the sum of the coefficients is very close to 1 and we do not reject the hypothesis that the matching function has CRS. Therefore,

[18] The translog functional form is

$$\log Q_{it} = \log Z_{it} + \eta_d \log D_{it} + \eta_u \log U_{it} + \eta_{bb} (\log D_{it})^2 + \eta_{uu} (\log U_{it})^2 + \eta_{bu} (\log D_{it}) \times (\log U_{it}) \,.$$

imposing this assumption leads to

$$\log\left(\frac{Q_{it}}{U_{it}}\right) = \eta_d \log\left(\frac{D_{it}}{U_{it}}\right) + \mu_i + \zeta_t + \epsilon_{it}\,. \tag{5}$$

whose estimate for the matching function elasticity η_d we report in column (3) of Table Table 1. The point estimate is 0.382.

Notes: effective buyers = (average viewings per buyer) × (raw number of buyers) = total viewings. Standard errors clustered at district level in parentheses. Significance level indicated according to * p<0.1, ** p<0.05, *** p<0.01.

As discussed in section 3, the data suggest our choice of monthly frequency for estimation. To verify robustness, we re-estimate the matching function to a quarterly aggregation of the data. Appendix Table B.2 shows that quarterly aggregation makes almost no difference to the baseline results.

Importance of search effort In the absence of data on search effort, researchers are constrained to estimating a matching function using raw buyers B as an input:

$$Q = \tilde{m}(B, U). \tag{6}$$

Estimation of equation (6) suffers from the problem of search effort being an omitted variable given that it may be correlated with matching-function inputs. Our data provide a direct measure of search effort to address this concern, allowing us to use effective buyers D as the input in the estimated matching function in equation (1).

Table 2 presents evidence in column (1) that search effort is positively correlated with the number of raw buyers. This shows how estimation of equation (6) could lead to an upward bias of the estimated raw-buyer elasticity. Indeed, column (2) confirms that the estimated coefficient of raw buyers is larger than the estimated coefficient of effective buyers in Table 1.[19]

Table 2: Importance of Search Effort

	log(search effort)	log(transactions)

Measures of search effort are also used in the two existing papers on estimating

[19]This difference is significant at the 99 percent confidence level based on a joint variance-covariance matrix of the two regression models (via seemingly unrelated regression).

the matching function for the housing market (Vidal, 2022; Badarinza et al., 2024). Different from our approach, they estimate (6) and use search effort as a control variable. However, a fundamental concern is that search effort is an outcome of decisions that also determine the numbers of buyers and sellers, rather than being an independent variable that can be held fixed. This issue is often referred to as a 'bad control' problem (see, for example, Angrist and Pischke, 2009). Even if buyers were as good as randomly assigned, holding fixed search effort and inventory when increasing the number of buyers likely leads to biased estimates. An increase in the number of buyers, which under constant inventory is not met with an increase in effort per buyer, is likely correlated with something unobserved that is simultaneously correlated with transactions and buyers, introducing a problem of endogeneity. To avoid the problem, but nonetheless account for search effort, it is advantageous to estimate (1) by using effective buyers D from (2) as the input, a combined measure of search effort and the number of buyers.

5 Event study

The OLS estimation with fixed effects above may not remove changes in matching efficiency that vary by district and time. To identify the elasticity of the matching function, we proceed by assuming a CRS Cobb-Douglas matching function and exploit a change in housing policy that removed restrictions on housing purchases. The removal of restrictions had a staggered rollout across districts. Using this quasi-experimental variation in treatment timing, we conduct event studies using the staggered difference-in-differences (DID) method. Following de Chaisemartin and D'Haultfœuille (2024), we implement an estimation method that allows heterogeneous treatment effects across districts.

5.1 Policy background and data

Before 2022, many large Chinese cities had two major restrictions on housing purchases. First, one's eligibility to purchase properties depends on one's *hukou* status. The Chinese *hukou* system (a household registration system) links residents to their registered birthplace, granting local *hukou* holders access to social benefits. Under this restriction, non-local *hukou* holders (essentially internal migrants) were required to provide proofs of local tax payment, social security contributions, or residency permits

for at least two years to be eligible to purchase properties. Second, there is a limit on the number of properties one can purchase, for both local and non-local *hukou* holders. These two restrictions could also interact with each other. For example, in the city of Nanjing, individuals with local *hukou* were not allowed to purchase a third property if they already owned two, while individuals with non-local *hukou* were not allowed to purchase a second property if they already owned one. In our data, four cities had both restrictions before 2022.

In 2022, the Ministry of Housing and Urban-Rural Development issued a central guide to stimulate the demand for housing. This guideline was motivated by a mix of factors: a slowdown in the property sector, widespread developer distress following the collapse of major developers including Evergrande, and the resulting threat to broader economic stability. In 2023, the Politburo Meeting, where China's top leaders set the policy agenda, sent a message to local cities that they should relax restrictions on housing purchases to increase demand. Following the central directions, the cities that had restrictions gradually removed the two restrictions from 2022 to 2024. The rollout of removals does not only vary across cities, but also across districts within a city.

Among the 15 cities in our data, four had housing purchase restrictions in place before 2022, covering a total of 34 districts. These restrictions were gradually removed across all 34 districts during 2022–2024. To construct the timing of removals at the district level, we conducted a comprehensive review of local housing policies from two sources. The first source is an extensive collection of policy documents issued by the Chinese central and local governments since 1949, compiled by PKU Law (https://PKULaw.com), an online platform hosted by Peking University Law School. The second source are local government websites, including city governments, development and reform commissions, and housing bureaus.

Our event-study analysis focuses on these 34 districts. The start of a removal in a district is defined as the month of either removing the eligibility restriction based on one's *hukou* status or removing the limit on the number of properties one can purchase, whichever comes first. We use the timing of the first removal in a binary estimation because the timing is relatively less likely to be anticipated. We also find that the policy announcement date and the enforcement date are the same in all districts. Figure A.5 shows the fraction of districts that had their first removal of housing restrictions from 2022 to 2024. The first removal was introduced in April 2022 and the last in June 2024. There is substantial variation in the timing of policy rollout across districts.

While the central government's motivation to stimulate demand was common to all districts, it does not explain the local variation in timing. The staggered removal of housing purchase restrictions reflects the interplay between central directives and local political economy. Since 2017, the central government has promoted the principle that "houses are for living in, not for betting", discouraging households from buying homes primarily as financial investments rather than places to live. Lifting purchase restrictions was necessary to stimulate demand, but risked being seen as encouraging investment purchases that the central government had discouraged. Suburban districts, where prices are lower and the investment case weak, could relax restrictions with little risk of increasing investment purchases and did so first. Each round of suburban relaxation legitimized the next step, generating implicit central endorsement for further action. Urban districts, where investment purchases are most expected to occur, could follow once this political ground had been cleared. Figure A.6 confirms the pattern geographically in which the removals began in the suburban districts first and then in the urban districts later. This pattern of staggered rollout across districts is consistent with China's broader practice of policy experimentation, in which reforms are first introduced in lower-stakes areas before wider adoption (Wang and Yang, 2025).

Table B.3 shows results consistent with this interpretation. Urban districts began removing restrictions approximately 11 months later than suburban districts. Importantly, neither pre-existing buyers to inventory ratio nor district-level exposure to developer distress (measured by the number of Evergrande projects by district) are correlated with the timing of removal. Other district characteristics including population, hukou composition, and homeownership rates are similarly uncorrelated. Together, these results suggest that the variation in timing reflects political considerations rather than underlying market conditions, which we discuss further in the context of the identification assumptions for a staggered DID design in the following sub-section.

5.2 Identification and estimation

Event study We begin by estimating the average treatment effect on the treated districts (ATT) of the policy change (i.e. the first removal of housing restrictions) on buyers, inventory, and transactions over event time using a staggered DID design. Due to the recent findings of a growing literature on the pitfalls of estimating the dynamic

effects of a binary (absorbing) treatment indicator W_{it}

$$y_{it} = \alpha_i + \alpha_t + \sum_{k=a}^{b} \phi_k W_{it}^k + \vartheta_{it} \tag{7}$$

via a two-way-fixed-effects estimation, we follow de Chaisemartin and D'Haultfœuille (2024) to estimate ATTs over event-time.[20] The primary coefficients of interest in (7) is given by the set of ϕ_k, which provide an ATT estimate of the difference in log outcome between k event months after treatment and the last month before treatment. Identification comes from contrasting this change with a control group. Since all 34 districts that had housing restrictions eventually removed them, the control group consists of districts in which restrictions have not yet been lifted at a given point in time (the "not-yet-treated" group). Districts that never had housing restrictions are excluded from all event-study analyses.

We need identification assumptions that are standard in the difference-in-differences method: most importantly the parallel trends assumption, i.e. in the absence of treatment, ϕ_k should be zero. The validity of this identification assumption is untestable, but we can assess whether our data are consistent with the parallel trends assumption in the pre-treatment period.

Figure 1 visualizes the event-study estimates on the number of effective buyers, inventory, and transactions. This figure provides two key results. First, we find no statistically significant differences in the trends of effective buyers, inventory and transactions between the treatment and control groups before the event of treatment. Second, the estimated coefficients in the first and third subfigures show that effective buyers and transactions increase to a relevant degree only from around 1 to 1.5 years after the removals of housing restrictions.[21] While the estimated coefficients are aligned, we acknowledge that the event study on effective buyers is slightly noisier between 11 to 18 months after policy removal, likely due to the absence of an effect on search effort, as discussed below. In contrast, we find no significant effect on inventory even two years after the policy change.

It is worth noting that the visualized chronology of events is consistent with the

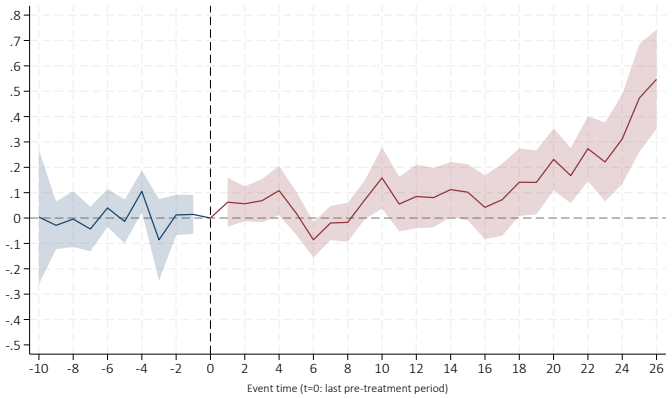

[20] We emphasize that with our binary treatment definition, the event-time coefficients after treatment from de Chaisemartin and D'Haultfœuille (2024) (DID_ℓ in their notation) are identical to ones by Callaway and Sant'Anna (2021) ($\theta_{es}(\ell - 1)$ in their notation). See the former paper for details.

[21] In order to put these magnitudes into context, we note that the magnitude of the changes in transactions is similar to the U.S. housing boom and bust documented in Ngai and Sheedy (2020).

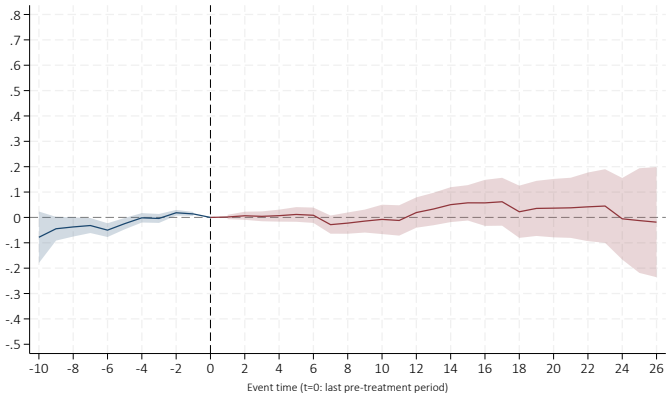

nature of housing search. At the time when housing restrictions are removed, potential buyers are likely locked into rental contracts, which typically last one to two years in Chinese cities. While these buyers may begin browsing available listings on the app soon after the policy change, they are unlikely to arrange in-person viewings until their rental terms approach expiration. Indeed, Figure A.8 shows that the number of clicks on the app increases right after the restrictions are removed.

Figure 1: Event study

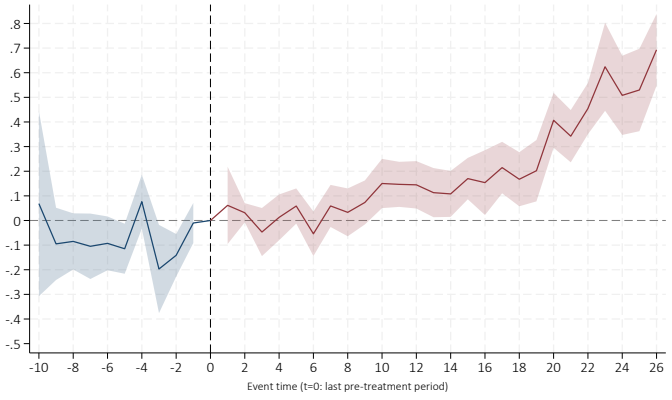

(a) log(effective buyers)

(b) log(inventory)

(c) log(transactions)

Notes: The bars indicate the 95 percent confidence intervals. Standard errors are clustered at the district level.

Assessing the validity of identification assumptions The validity of the event study estimation is subject to a set of identification assumptions for the staggered DID design. A key assumption is parallel trends in the counterfactual, untreated outcome: in the absence of the treatment, the trajectory of the outcome variable has to be parallel between the treatment and control groups. We discuss two potential threats to this assumption and how we address them below.

The first concern relates to our finding in section 5.1 that urban districts tend to start the removals later than suburban districts. If potential buyers in urban areas had anticipated the incoming policy change and begun to respond before the policy took effect, we would expect viewings to have started increasing in urban districts before the event of treatment. However, the absence of pre-trends in Figure 1 does not support this concern.

The second concern could arise from spillovers from treated to not-yet-treated districts via possible anticipation effects among local residents who were not constrained by the previous *hukou*-based housing restriction. Once some districts started to remove the restriction, local residents in not-yet-treated districts might expect that their districts would soon follow. Based on market activity in already-treated districts the not-yet-treated districts could appear as relatively cheaper, potentially attracting additional demand before their own restrictions were removed. However, we argue that if these spillovers would impact districts in the control group differentially, we would expect to see violations of parallel trends. Figure 1 did not reveal these violations. Only in case of perfectly identical spillovers to districts in the control group this would fail. In that case, estimated treatment effects would likely be an underestimation of the real effect of the policy. However, as we will explain shortly, our approach of exploiting the policy removal to estimate the elasticity of the matching function would not be biased by a uniform underestimation of all dynamic effects.

The remaining assumption is that other housing policies during our study period do not confound our findings in Figure 1. To assess this assumption, we conducted a comprehensive search of all other housing policies in our area of study during 2022-2024, from the same sources described in section 5.1 (i.e. local government websites and PKU law). First, national policies to reduce mortgage interest rates did not vary across regions and are therefore controlled for by the time fixed effects. Second, no other housing policies had a staggered rollout within-city and between districts. Third, two policies that had a staggered rollout by city are potentially concerning: one

provided lower mortgage rates to buyers who used their provident fund for the down payment, and the other subsidized a small number of buyers with talent status in their housing purchases. In robustness tests, we control for the city-level rollout of these two additional policies. Figure A.9 shows that all results of the event study are robust to including other policies.

Estimation of the elasticity As an evaluation of the policy change is not the primary focus of this paper, we will explain in the following how we use the event studies to provide a more reliable estimate of the elasticity of the matching function. In a quasi-experimental design, let Q be defined as the observed transactions and Q' as the counterfactual transactions had there been no removals of housing restrictions, which can be written as follows:

$$Q = ZD^{\eta_b}U^{\eta_u} \quad \text{and} \quad Q' = Z'D'^{\eta_b}U'^{\eta_u}\,. \tag{8}$$

The staggered rollout of the policy enables us to identify and estimate ATTs by cohort-time, where a cohort is defined as the set of districts sharing the first period of treatment:

$$ATT_{cohort,time} = E[Y_{cohort,time} - Y'_{cohort,time}|\text{ Treatment }]\,, \tag{9}$$

where Y could represent the natural log of transactions Q, or effective buyers D, or inventory U. Treatment status is equal to one from the month of the first housing restriction removal, and zero otherwise.

We focus on Equation (10) below where the ratio of transactions to inventory is the outcome for two reasons. First, the event study shows no significant policy effect on inventory (Figure 1). Second, with a single policy treatment, the induced variation can identify at most one parameter. Therefore, separately recovering both η_b and η_u is not feasible regardless of whether inventory responds to the policy. We thus assume CRS and work with log(Q/U) and log(D/U), which directly delivers the elasticity of interest η_b. Omitting cohort-time notation for brevity, we can write $\mathbb{E}\Big[\log(Q/U) - \log(Q'/U')\mid$

Treatment $\Big]$ as:

$$\underbrace{\mathbb{E}\left[\log\left(\frac{Q/U}{Q'/U'}\right) \mid \text{ Treat. }\right]}_{\text{ATT of } Q/U} = \mathbb{E}\Big[\log\left(\frac{Z}{Z'}\right) \mid \text{ Treat. }\Big] + \eta_b \underbrace{\mathbb{E}\left[\log\left(\frac{D/U}{D'/U'}\right) \mid \text{ Treat. }\right]}_{\text{ATT of } D/U}. \tag{10}$$

A regression of cohort-time ATTs of $\log(Q/U)$ on cohort-time ATTs of $\log(D/U)$ identifies η_d under weaker assumptions than a simple regression of Equation (4). Rather than requiring district-time-specific changes in matching efficiency to be uncorrelated with changes in buyers and inventory, the identification here only requires the policy's effect on D/U to be uncorrelated with its effect on matching efficiency Z. Moreover, if spillovers from treated to not-yet-treated districts uniformly reduce all estimated ATTs, identification of η_d remains unaffected, since a uniform level shift in both the outcome and regressor leaves the estimated slope unchanged.[22]

To address the remaining concerns about the correlation between the ATT of D/U and the effect on Z, we include cohort and time fixed effects, which absorb district-specific and common time-varying confounders in matching efficiency. We therefore estimate:

$$(\text{ATT of Q/U})_{cohort,t} = \mu_{cohort} + \zeta_t + \eta_d \, (\text{ATT of D/U})_{cohort,t} + \epsilon_{cohort,t}\,, \tag{11}$$

where we include for each cohort all estimated ATTs from the period of policy change onward.[23]

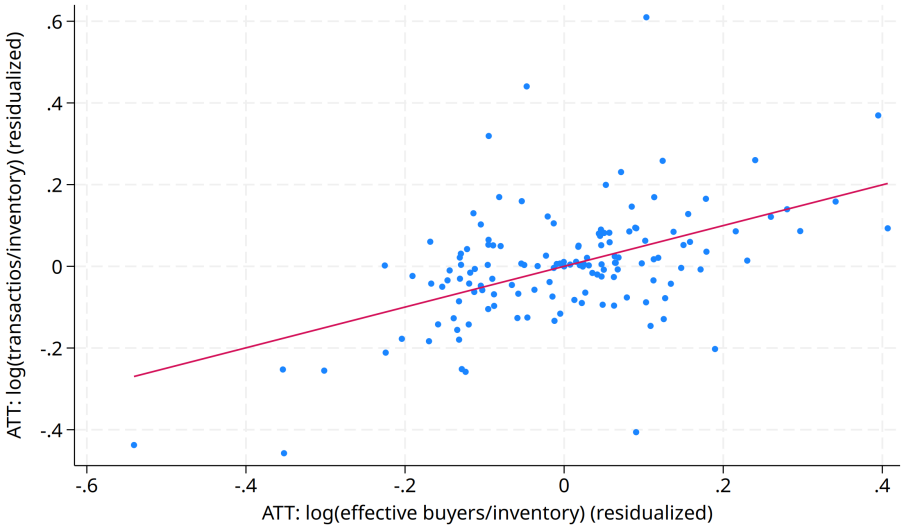

The results are provided in Table 3 and visualized in Figure 2. Assuming a CRS structure and the discussed identifying assumptions lead to an estimate for $\eta_d = 0.499$. The number of observations in this regression refers to the number of time periods we observe each cohort after treatment. The number of cohorts used for estimation is equal to seven, while the maximum number of periods is 26. All of these cohort-time specific ATTs are visualized in Figure 2 (after residualizing using as regressors only fixed effects). The linear slope in this figure is identical to the estimated coefficient

[22] In Appendix C we discuss how under different assumptions than we impose on our main specification, an alternative way to yield an estimate of η_d is given by dividing aggregate weighted averages of ATTs of the left-hand side by aggregate weighted averages of ATTs of the right-hand side of (10).

[23] We restrict to periods after treatment because under the assumption of parallel trends, adding the pre-treatment periods for both the dependent and independent ATTs would imply adding (noisy) zeros on both sides of the estimating equation, which serves no purpose. For a test of parallel trends, we refer to Figure 1.

from the table based on the Frisch–Waugh–Lovell theorem.

Figure 2: Scatterplot of ATT estimates by group and time

Notes: The data points refer to residualized estimated ATTs on cohort-time level. After estimating the effect of the policies on either log-transformed transactions over inventory (vertical axis) or log-transformed effective buyers over inventory (horizontal axis), these dynamic effects on cohort-time level were regressed on cohort and time fixed effects. The figure visualized the residuals of these regressions together with a linear fit, which based on the Frisch–Waugh–Lovell theorem, has a slope identical to the estimated coefficient shown in Table 3.

Table 3: DID estimation: estimating elasticity

	$\text{ATT}_{d,t}$ log(transactions/inventory)
$\text{ATT}_{d,t}$ log(effective buyers/inventory)	0.499***

Notes: effective buyers = (average viewings per buyer) × (number of buyers) = viewings. Dependent and independent variable are both estimates of ATTs over cohort and time. A cohort consists of all districts sharing the same first time period of treatment. Bootstrap standard errors in parentheses. Significance level indicated according to * p<0.1, ** p<0.05, *** p<0.01.

6 Conclusion

The modelling of search frictions in macroeconomics has built on the key innovation of the matching function, which has become pervasive in analyses of the labour market. This theoretical research has been supported by an extensive empirical literature that has estimated labour-market matching functions. Research on the interactions between frictional housing markets and macroeconomics has often assumed a CRS Cobb-Douglas matching function, but has lacked empirical evidence on the key elasticity parameter.

Our paper fills this crucial gap in the literature using a novel dataset with information on buyers and their search behaviour as well as an event study that provides exogenous shifts in buyers. We find evidence that the housing-market matching function has an elasticity with respect of demand of around 0.5 for a CRS Cobb-Douglas function:

$$\boxed{Q = ZD^{0.5}U^{0.5}}.$$

C Wald-Style Estimator

In this section we dicuss an alternative route to identify the elasticity of interest by showing a Wald-style approach of taking the ratio of two weighted averages of cohort-time-specific ATTs is posing stronger assumptions on our identification.

Consider as starting point again

$$E\Big[\log\big(\frac{Q/U}{Q'/U'}\big)|Treatment\Big] = E\Big[\log\big(\frac{Z}{Z'}\big)|Treatment\Big] + \eta_b E\Big[\log\big(\frac{D/U}{D'/U'}\big)|Treatment\Big] \tag{12}$$

which we can re-write with some simplification to

$$\begin{aligned} ATT^{Q/U}_{cohort,time} &= ATT^{Z}_{cohort,time} + \eta_b ATT^{D/U}_{cohort,time} \\ \equiv \delta^{Q/U}_{g,t} &= \delta^{Z}_{g,t} + \eta_b \delta^{D/U}_{g,t} \end{aligned} \tag{13}$$

Our current approach is to get estimates on cohort-time level for $\delta^{Q/U}_{g,t}, \delta^{D/U}_{g,t}$ and then regress the previous equation with fixed effects. One should realize that for all (g,t) combinations for which it holds that $\delta^{Z}_{g,t} = 0$, we can also get

$$\eta_b = \frac{\delta^{Q/U}_{g,t}}{\delta^{D/U}_{g,t}} \tag{14}$$

Whenever in a given cohort-time combination $\delta^{Z}_{g,t} \neq 0$, this will not be true. The question is whether a weighted combination of $\delta^{Q/U}_{g,t}$ divided by a weighted combination for $\delta^{D/U}_{g,t}$ can also give us η_b. Let

$$\begin{aligned} \delta^{Q/U} &\equiv \sum_g \sum_t \omega(g,t)\delta^{Q/U}_{g,t} \\ \delta^{D/U} &\equiv \sum_g \sum_t \omega(g,t)\delta^{D/U}_{g,t} \end{aligned} \tag{15}$$

Then it holds that

$$\begin{aligned} \frac{\delta^{Q/U}}{\delta^{D/U}} &= \frac{\sum_g \sum_t \omega(g,t)\delta^{Q/U}_{g,t}}{\sum_g \sum_t \omega(g,t)\delta^{D/U}_{g,t}} \\ &= \frac{\sum_g \sum_t \omega(g,t)\big(\delta^{Z}_{g,t} + \eta_b \delta^{D/U}_{g,t}\big)}{\sum_g \sum_t \omega(g,t)\delta^{D/U}_{g,t}} \\ &= \frac{\sum_g \sum_t \omega(g,t)\delta^{Z}_{g,t}}{\sum_g \sum_t \omega(g,t)\delta^{D/U}_{g,t}} + \eta_b \frac{\sum_g \sum_t \omega(g,t)\delta^{D/U}_{g,t}}{\sum_g \sum_t \omega(g,t)\delta^{D/U}_{g,t}} \\ &= \frac{\sum_g \sum_t \omega(g,t)\delta^{Z}_{g,t}}{\sum_g \sum_t \omega(g,t)\delta^{D/U}_{g,t}} + \eta_b \end{aligned} \tag{16}$$

Therefore, we get that

$$\frac{\delta^{Q/U}}{\delta^{D/U}} = \eta_b \iff \sum_g \sum_t \omega(g,t)\delta^Z_{g,t} = 0 \tag{17}$$

This can be satisfied in two scenarios:

1. $\delta^Z_{g,t} = 0 \, \forall g, t$, that is, the average effect of the policy on Z is zero in all cohorts. In principle, one could still have effects in single districts, but only to the extent that these effects cancel themselves out to zero within cohorts.

2. In some cohort-time combinations, the effect of the policy is negative while in others it is positive and such that these effects perfectly cancel each other.

In contrast, in our main specification we are neither (1) assuming that the effect must be zero in all cohort-time periods, nor (2) that it must be negative for some cohorts and time periods and at the same time perfectly cancel with positive effects from other cohorts. However, we are assuming that the effects on Z and D/U are uncorrelated.
