What Is the Carbon Premium a Premium On?*

Marcin Kacperczyk

April 16, 2026

Abstract

I develop an asset-pricing framework in which climate risk premia are determined by the price of risk and a mapping from firm fundamentals into cash-flow exposure. While the price of risk reflects aggregate conditions, priced characteristics are governed by how climate and policy shocks enter firm cash flows and need not coincide with standard emissions-based metrics. For example, emission intensity is sufficient for pricing climate risk only under restrictive homogeneity and scale-invariance conditions. I derive testable scale and spanning restrictions and reject them in international data. The framework implies that commonly used measures recover *projections* of underlying exposure, reconciling conflicting evidence on climate risk premia. This gap between measured characteristics and underlying exposure has implications for the measurement of climate risk and the allocation of capital.

1 Introduction

Investors, regulators, and policy makers increasingly speak about a carbon premium or greenium in asset prices. Getting its measurement right matters: portfolio screens, regulatory taxonomies, and corporate discount rates all depend on correctly identifying which firm attributes carry climate risk. Yet there is little agreement on what this premium is a premium on. Empirical studies proxy climate exposure using absolute emissions or changes in emissions (e.g., Bolton and Kacperczyk (2021, 2023)), emissions scaled by firm value or revenue (Pedersen (2025)), sectoral classifications (Pastor et al. (2022)), or composite transition-risk scores (e.g., Sautner et al. (2023), Cenedese et al. (2024), Eskildsen et al. (2024)). Consistent with this lack of agreement, pairwise correlations across commonly used climate risk measures are far from perfect, suggesting that these proxies capture distinct dimensions of underlying exposure rather than a single priced object. The coexistence of these approaches therefore leaves a basic issue unresolved: which firm characteristics actually govern climate risk premia in equilibrium?

This disagreement reflects a deeper model-selection problem. The finance literature has largely evaluated climate characteristics by asking which proxies predict returns. But expected returns are determined by how climate and policy shocks enter firm cash flows. Different economic mechanisms imply different cash-flow exposure functions and therefore different candidate sufficient statistics for pricing climate risk. Absent a mapping from economic mechanisms to value-normalized exposure, empirical comparisons across alternative measures remain difficult to interpret, as different characteristics recover projections of distinct underlying exposures rather than a common priced object.

I address this model-selection problem by developing a framework that characterizes which firm characteristics can serve as sufficient statistics for pricing climate risk. Climate and policy shocks affect firms through dollar cash-flow exposures summarized by exposure functions $g(Z_{i,t})$ that map firm characteristics into dividend sensitivities. Because returns are defined per unit of invested wealth, equilibrium risk premia load on normalized exposures $g(Z_{i,t})/V_{i,t}$, where $V_{i,t}$ denotes firm value. Identifying priced characteristics therefore requires identifying the underlying exposure function implied by the economic mechanism.

I apply this framework to emission intensity, the leading policy-relevant and widely used measure of climate risk, to illustrate its implications. This application yields a characterization that emission intensity $X_{i,t}/V_{i,t}$ is a sufficient statistic for pricing climate risk only under two joint re-

strictions. First, primitive cash-flow sensitivities must scale proportionally with firm size, so that the underlying exposure is homogeneous of degree one in emissions and firm value. Second, priced sensitivities must be invariant across firms with the same emission intensity, implying that two firms with identical intensity carry the same value-normalized exposure regardless of their scale or other characteristics. Under these joint conditions, expected returns depend only on emission intensity and not separately on the underlying primitives from which it is constructed. These restrictions generate falsifiable cross-sectional implications—spanning and scale invariance—that can be tested directly in the data. More generally, this characterization illustrates how candidate characteristics correspond to specific assumptions about the underlying exposure function.

An important implication of this framework is that market structure affects the equilibrium *price* of climate risk, but not the mapping from firm fundamentals into priced exposure. Specifically, the extent to which climate risks are spanned and the degree of heterogeneity in climate concern determine the price of risk, while the function $g(Z_{i,t})$ is governed by how shocks enter firms' cash flows. As a result, emission intensity appears as a priced characteristic only under the restrictive conditions that make value-normalized sensitivities collapse to $X_{i,t}/V_{i,t}$, rather than as a general implication of equilibrium pricing.

To characterize how market structure determines the equilibrium price of climate risk, I develop a tractable model with heterogeneous investors who face unspanned climate damages and differ in their concern about those damages. The model delivers a simple benchmark in which firms' cash-flow sensitivities to climate or policy shocks scale with emission levels, generating a factor structure in which expected returns reflect value-normalized sensitivities together with an equilibrium price of risk. In this benchmark, the price of risk admits a decomposition into a component that compensates investors for bearing unhedgeable climate risk and a component driven by heterogeneous climate concern.

Building on this structure, I embed the model in a unified linear-factor framework for climate risk, including both physical and transition components. In this representation, expected excess returns take the form

$$E_t[R_{i,t+1} - R_{f,t}] \;=\; \sum_k \lambda_{k,t} \, \frac{g_k(Z_{i,t})}{V_{i,t}},$$

where each factor k captures a distinct channel of climate risk—such as policy shocks, physical damages, or technology changes—and $g_k(Z_{i,t})$ summarizes how that channel enters firm i's dollar cash flows. This representation provides a systematic way to assess when a given scalar characteristic

can summarize the multidimensional exposure $g_k(Z_{i,t})/V_{i,t}$ across factors. In general, many economically natural mechanisms violate the homogeneity and scale-invariance conditions required for intensity sufficiency, so that emission intensity need not summarize priced exposure in equilibrium.

An important implication of the framework is that misidentifying the relevant exposure function can distort both pricing and real outcomes. When investors or regulators rely on characteristics that do not correspond to $g(Z_{i,t})/V_{i,t}$, equilibrium prices reflect projections onto the chosen metric rather than underlying exposure. This misalignment can direct capital toward firms that appear low-risk under the selected characteristic while leaving true exposure unchanged, and can induce firms to optimize measured metrics rather than the underlying drivers of climate risk. For example, efficiency improvements can increase equilibrium exposure if they induce higher output and emissions, illustrating how improvements in commonly used measures need not correspond to reductions in priced climate risk.[1]

I test these implications in the context of emission intensity using an international panel of firms with Scope 1 emissions. Consistent with the model's predictions, emission intensity fails to span the cross-section of returns once emission levels are included, and its pricing is not invariant to firm scale, violating scale invariance. Return-forecasting regressions show that absolute emissions are positively and robustly related to future returns, while emission intensity becomes insignificant conditional on levels and adds no explanatory power. In joint specifications that condition on emission intensity, firm characteristics, and extensive country, industry, and time fixed effects, a one-standard-deviation increase in log Scope 1 emissions predicts a 0.35% increase in next-month expected returns (about 4.2% annualized), with effects remaining significant over the subsequent year. This pricing asymmetry persists even within narrow size classes: within firms of similar value, variation in emission levels is associated with higher expected returns even after controlling for emission intensity. Moreover, the pricing of intensity varies systematically with firm scale, directly rejecting the scale-invariance restriction implied by intensity sufficiency.

Importantly, the objective of the empirical analysis is not to identify a "best" proxy for climate risk premia. Rather, the goal is to provide a framework and a set of testable restrictions that any candidate characteristic must satisfy in order to serve as a sufficient statistic for priced exposure. From this perspective, my empirical results should be interpreted as evaluating the validity of specific measures, not as establishing a definitive alternative. The rejection of a given characteristic,

[1] This mechanism is related to the Jevons paradox (Jevons, 1865), whereby improvements in efficiency can increase total resource use through behavioral and equilibrium responses.

such as emission intensity, therefore does not imply that another proxy is universally sufficient, but instead highlights the need to discipline measurement by the underlying economic mechanisms that determine exposure.

A natural implication of this framework is that aggregating across multiple measures can obscure the underlying economic object being priced. Such aggregation reduces measurement error only if the underlying signals correspond to the same economic object. When different measures instead originate from distinct economic mechanisms, such as policy exposure, technology choice, regulatory compliance, or investor preferences, aggregation obscures interpretation rather than improving it. In that case, it becomes unclear what economic exposure the resulting score is intended to proxy.

Finally, the framework clarifies the role of emission intensity in policy discussions. In complete-markets environments, such as in the sustainable-discount-rate literature, intensity emerges naturally as a sufficient statistic for implementing policy objectives because cash-flow distortions scale proportionally with emissions. This provides a rationale for the widespread use of intensity-based metrics in regulation and policy design. The analysis in this paper shows that these conditions are restrictive. While intensity is appropriate for measuring emissions per unit of economic activity, it does not, in general, summarize the cross-sectional variation in priced climate exposure that determines equilibrium risk premia.

Overall, the paper makes three contributions. First, it reframes the measurement of climate risk premia as a problem of identifying value-normalized exposure functions $g(Z_{i,t})/V_{i,t}$ that map firm characteristics into priced cash-flow sensitivities. This perspective implies that commonly used characteristics are informative only to the extent that they recover the underlying exposure function, rather than serving as primitives of the pricing relation. Second, it provides a general characterization of when a given scalar characteristic is a sufficient statistic for priced exposure. In particular, a characteristic must recover $g(Z_{i,t})/V_{i,t}$ up to scale, which imposes sharp and testable cross-sectional restrictions—spanning and scale invariance. These restrictions translate the distinction between characteristics and exposure functions into empirically implementable tests. Third, it shows that economically natural policy and technology mechanisms generate exposure functions that violate these restrictions, so that commonly used measures need not summarize priced risk. As a result, empirical proxies for climate risk reflect projections of underlying exposure onto selected characteristics rather than the exposure itself. This misalignment introduces systematic measurement error and can distort capital allocation, including in settings where investors or regulators rely on composite ESG measures that aggregate across heterogeneous exposure channels.

Related Literature. This paper relates to several strands of the climate-finance and sustainable-investing literature. Theoretically, the framework relates to equilibrium models with heterogeneous ESG preferences. Pastor et al. (2021) develop a static equilibrium in which an exogenous greenness characteristic enters investors' utility and generates a green factor and greenium in expected returns. Pedersen et al. (2021) construct an ESG-efficient frontier and an ESG-adjusted CAPM with heterogeneously ESG-motivated investors, showing how ESG scores affect equilibrium Sharpe ratios and expected returns. Zerbib (2022) and De Angelis et al. (2023) analyze sustainable investing when some investors internalize environmental externalities, deriving taste and exclusion premia in which green investors' portfolio tilts raise brown firms' cost of capital. Dangl et al. (2025) develop a unified framework with different social preference types and establish that such preferences can have substantial real effects even when observed cost-of-capital gaps are small. These papers share the idea that heterogeneous ESG or climate preferences generate equilibrium premia, but typically take the relevant ESG or environmental metric as given. My framework instead endogenizes green and brown classifications as equilibrium exposure functions–priced objects determined by how climate and policy shocks enter cash flows–rather than treating them as exogenous firm types.

A related literature examines sustainable-discount-rate and social-cost-of-carbon frameworks. Pedersen (2025) shows that in a complete-markets planner world, the sustainable-discount-rate wedge implementing the social optimum is proportional to firms' emission intensity. Chittaro et al. (2025) demonstrate that in a frictionless representative-agent economy, a carbon tax is equivalent to a return schedule increasing linearly in emission intensity. Empirically, Pastor et al. (2025a) introduce a firm's carbon burden–the present value of social costs of future emissions–and find that firms with higher carbon burdens have higher costs of capital. In my framework, such SCC-based burdens correspond to particular exposure functions $g(Z_i)$, and the analysis clarifies when SCC-based objects serve as priced characteristics in equilibrium versus planner implementation.

Empirically, a large literature documents correlations between carbon characteristics and expected returns. Studies use emission levels and changes thereof (Bolton and Kacperczyk, 2021, 2023), emission intensity (Pastor et al., 2022; Eskildsen et al., 2024), composite ESG scores, and text-based climate exposure measures (Sautner et al., 2023). Pastor et al. (2025b) survey the sustainable-investing literature and highlight as an open question which ESG attributes are actually priced in equilibrium. A related challenge is that ostensibly similar ESG characteristics can be constructed very differently across data providers (Berg et al., 2022). I take a structural approach rather than proposing new emission metrics: which emission-based characteristics can

legitimately serve as sufficient statistics for exposure to priced climate factors? The framework delivers testable restrictions, scale invariance and spanning, that discipline when emission intensity suffices for equilibrium pricing and when alternative exposure measures are consistent with the data.

The remainder of the paper is organized as follows. Section 2 develops a tractable incomplete-markets environment with heterogeneous investors, specifying firms, cash flows, and preferences in the presence of unspanned climate risk. Sections 3 and 4 build on this environment to characterize equilibrium pricing in a general linear-factor framework and derive the conditions under which a given characteristic, such as emission intensity, is sufficient to summarize priced exposure. Section 5 studies economically motivated specifications that violate these conditions, illustrating how different mechanisms generate distinct priced characteristics. Section 6 tests the model's cross-sectional restrictions—spanning and scale invariance—using international firm-level data. Section 7 discusses implications for measurement, capital allocation, and policy. Section 8 concludes.

2 A Simple Model with Heterogeneous Investors and Climate Risk

Consider a two-period economy, with $t = 0, 1$. Uncertainty is represented by a probability space Ω with probability measure $\mathbb{P}$. The economy features a single physical consumption good that serves as numeraire, N firms indexed by $i = 1, \ldots, N$, and H households indexed by $h = 1, \ldots, H$. In addition to the N risky assets, a risk-free asset in zero net supply with gross return $R_f > 0$ is available.

2.1 Emissions, climate shock, and damages

Each firm i has a fixed level of emissions $X_i \geq 0$ at date 0, which determines its exposure to the climate shock realized at date 1. Aggregate emissions are

$$\bar{X} \equiv \sum_{i=1}^{N} X_i. \tag{2.1}$$

The economy is exposed to a one-dimensional aggregate climate or policy shock $\zeta : \Omega \to \mathbb{R}$ with

$$\mathbb{E}[\zeta] = 0, \qquad \mathrm{Var}(\zeta) = \sigma_\zeta^2 > 0. \tag{2.2}$$

I assume ζ is normally distributed and all payoffs are jointly normal.

Climate damages, Γ, are linear in ζ and proportional to aggregate emissions:

$$\Gamma(\zeta) \equiv \kappa \bar{X}\, \zeta, \qquad \kappa > 0. \tag{2.3}$$

Equation (2.3) is a reduced-form representation of the idea that the realization of the climate shock ζ scales damages in proportion to $\bar{X}$. The linear specification serves as a convenient benchmark, which I relax in Internet Appendix A by allowing for nonlinear and more general damage specifications.

2.2 Firms and cash flows

Firm i issues a single share of equity in fixed supply. Its date-1 dividend in state $\omega \in \Omega$ is

$$D_i(\omega) = \mu_i + \eta X_i \zeta(\omega), \tag{2.4}$$

where $\mu_i \in \mathbb{R}$ is a deterministic component and $\eta > 0$ is a technology parameter common across firms. The shock ζ represents aggregate climate news and can be interpreted broadly as either transition or physical climate risk. When ζ captures transition risk—such as unexpected changes in carbon pricing, regulation, or clean technology—the linear loading on emissions has a direct interpretation: higher-emission firms experience larger cash-flow impacts from per-unit policy or technology shocks. When ζ instead reflects physical climate damages, the interpretation is more indirect. Physical damages affect firms primarily through aggregate productivity, demand, and policy responses rather than through firm-specific losses alone. Emissions therefore serve as a reduced-form proxy for exposure to climate-related macroeconomic or policy responses across sectors, for example due to higher energy intensity, regulatory incidence, or reliance on carbon-intensive inputs. Equation (2.4) should therefore be viewed as a benchmark specification that isolates a simple exposure channel in which cash-flow sensitivity is proportional to emissions. Later sections relax this assumption and allow the exposure function $g(Z_{i,t})$ to depend on richer firm characteristics, illustrating how alternative economic mechanisms generate different priced characteristics.

I further denote V_i as the date-0 market value of firm i's equity, and define the gross return

$$R_i(\omega) \equiv \frac{D_i(\omega)}{V_i}. \tag{2.5}$$

2.3 Households, preferences, and market structure

Household h has date-0 financial wealth $W_0^h > 0$. At $t = 0$, the household chooses a portfolio $\theta^h = (\theta_1^h, \ldots, \theta_N^h)^\top$ in the N risky assets and invests an amount b^h in the risk-free asset, subject to the budget constraint

$$\sum_{i=1}^{N} V_i \theta_i^h + b^h = W_0^h. \tag{2.6}$$

Date-1 consumption of household h in state ω is then given by

$$C_1^h(\omega) = R_f\, b^h + \sum_{i=1}^{N} \theta_i^h D_i(\omega), \tag{2.7}$$

where R_f denotes the gross risk-free return.

Households have exponential (CARA) preferences over climate-adjusted consumption,

$$U^h = \mathbb{E}\left[-\exp\left(-\alpha_h \big(C_1^h(\omega) - \phi_h \Gamma(\zeta) \big) \right) \right], \tag{2.8}$$

where $\alpha_h > 0$ is the coefficient of absolute risk aversion and $\phi_h \geq 0$ indexes household h's climate concern. The term $\phi_h \Gamma(\zeta)$ captures disutility from aggregate climate damages $\Gamma(\zeta)$, with $\phi_h = 0$ corresponding to a purely financial (brown) investor and $\phi_h > 0$ to a climate-conscious (green) investor. Importantly, $\Gamma(\zeta)$ is not a direct financial loss borne uniformly through the household budget constraint. Rather, it is an aggregate damage state that enters utility through climate concern, capturing disutility from the realization of global climate outcomes even when the associated physical or economic losses are largely external to the household's own consumption stream.

A canonical example of unspanned climate risk arises from global damages that affect households' welfare but are not directly traded in financial markets. Sea-level rise, biodiversity loss, or health damages from extreme weather may reduce welfare without mapping one-to-one into the cash flows of traded firms. Investors therefore care about these outcomes but cannot construct portfolios that perfectly hedge them. This wedge between welfare-relevant climate damages and traded payoffs generates an incomplete-markets pricing kernel.

Because these damages are non-tradable and investors differ in (α_h, ϕ_h), markets are incomplete with respect to climate risk and the stochastic discount factor that prices traded assets reflects a wealth-weighted aggregation of heterogeneous marginal rates of substitution rather than the planner's sustainable discount factor.[2] The resulting priced climate characteristic is therefore

[2] I use the term incomplete markets as shorthand for environments in which climate damages are non-tradable and

an equilibrium object, a function of firm exposures, and the associated premium admits a decomposition into a risk-based brown component and a preference-driven green component, as formalized in Section 3.1.

3 Equilibrium Pricing with Unspanned Climate Risk

This section develops the core framework of the paper. Climate and transition risk affect asset prices through their impact on firms' cash flows, and expected returns are determined by value-normalized exposure functions that map firm characteristics into sensitivities to climate and policy shocks. I formalize this mapping using exposure functions $g(Z_{i,t})$ that translate firm characteristics into dollar sensitivities to climate and policy shocks. This representation accommodates multiple, overlapping channels through which climate risk operates. Emissions, technology, demand conditions, and policy exposure can all affect how firms load on aggregate shocks, and different economic mechanisms imply different exposure functions. As a result, no single characteristic, such as emission intensity, is guaranteed to summarize priced exposure a priori. The framework yields a linear factor representation in which expected returns depend on value-normalized exposure functions. This representation provides a systematic way to assess when a given characteristic is sufficient for pricing climate risk and when it is not.

3.1 Market incompleteness and non-tradable climate damages

The only traded risky payoffs are the N stocks with dividends given by (2.4). There is a single aggregate climate shock ζ, and I allow for additional idiosyncratic shocks in μ_i, but for the derivations below I focus on the one-factor structure (2.4).

Building on the environment in Section 2, markets are incomplete in that there is no portfolio of traded assets whose payoff replicates the damage term $\Gamma(\zeta)$. Equivalently, ζ is not fully spanned by the space of traded payoffs once the non-pecuniary climate term in preferences is taken into account. Put differently, markets are complete for financial payoffs, but the climate damage term in utility is non-tradable, so the SDF is not the MRS of someone who internalizes the externality in a planner sense.

Nevertheless, equilibrium asset pricing remains well defined. There exists a unique stochastic

heterogeneously valued across investors. Formally, the climate externality reflects a missing market, while heterogeneity in concern implies that the resulting damage risk is unspanned by traded assets, leading to an incomplete-markets pricing kernel.

discount factor m that prices all traded assets, but the incomplete spanning of $\Gamma(\zeta)$ implies that this pricing kernel cannot be interpreted as the marginal rate of substitution of a representative planner who internalizes the externality. This distinction from the complete-markets benchmark is central for understanding how climate risk is priced in equilibrium.

3.2 Equilibrium pricing of climate risk

Mean-variance representation Under CARA-exponential utility and joint normality, maximizing expected utility (2.8) is equivalent to maximizing a mean-variance objective. Substituting (2.3), (2.4), and (2.7), we have

$$C_1^h - \phi_h \Gamma(\zeta) = b^h R_f + \sum_{i=1}^N \theta_i^h \mu_i + \Big(\sum_{i=1}^N \theta_i^h \eta X_i - \phi_h \kappa \bar{X} \Big) \zeta.$$

Thus

$$C_1^h - \phi_h \Gamma(\zeta) = A_h + B_h \zeta,$$

where

$$A_h \equiv b^h R_f + \sum_{i=1}^N \theta_i^h \mu_i, \qquad B_h \equiv \sum_{i=1}^N \theta_i^h \eta X_i - \phi_h \kappa \bar{X}.$$

The mean-variance representation of (2.8) becomes

$$U^h = -\exp\Big(-\alpha_h \Big(\mathbb{E}[A_h] - \tfrac{\alpha_h}{2} \mathrm{Var}(B_h \zeta) \Big) \Big),$$

so household h chooses (θ^h, b^h) to maximize

$$\mathbb{E}[C_1^h - \phi_h \Gamma(\zeta)] - \frac{\alpha_h}{2} \mathrm{Var}[C_1^h - \phi_h \Gamma(\zeta)]. \tag{3.1}$$

Since b^h only enters linearly and serves to satisfy the budget constraint, the key choice is the vector θ^h.

Using $\mathbb{E}[\zeta] = 0$ and $\mathrm{Var}(\zeta) = \sigma_\zeta^2$, objective (3.1) becomes

$$\sum_{i=1}^N \theta_i^h (\mu_i - V_i R_f) \; - \; \frac{\alpha_h}{2} \sigma_\zeta^2 \Big(\sum_{i=1}^N \theta_i^h \eta X_i - \phi_h \kappa \bar{X} \Big)^2.$$

First-order conditions and equilibrium prices The first-order condition for θ_i^h is

$$\mu_i - V_i R_f - \alpha_h \sigma_\zeta^2 \Big(\sum_{j=1}^{N} \theta_j^h \eta X_j - \phi_h \kappa \bar{X} \Big) \eta X_i = 0, \qquad i = 1, \ldots, N. \tag{3.2}$$

Define

$$\delta_h \equiv \sum_{j=1}^{N} \theta_j^h \eta X_j - \phi_h \kappa \bar{X}.$$

Then (3.2) is equivalently

$$\mu_i - V_i R_f = \alpha_h \sigma_\zeta^2 \delta_h \eta X_i, \qquad i = 1, \ldots, N. \tag{3.3}$$

Since the left-hand side does not depend on h, equilibrium requires $\alpha_h \sigma_\zeta^2 \delta_h$ to be common across households with interior holdings.

Proposition 1. *In any competitive equilibrium with $\eta > 0$, there exists a scalar λ such that*

$$\mu_i - V_i R_f = \lambda \eta X_i, \qquad i = 1, \ldots, N, \tag{3.4}$$

and for every household h,

$$\delta_h = \frac{\lambda}{\alpha_h \sigma_\zeta^2}. \tag{3.5}$$

Proof is in Appendix A.1.

Equation (3.4) is a pricing relation in dollar units. Dividing by V_i yields the corresponding return representation,

$$\mathbb{E}[R_i] - R_f = \lambda \eta \frac{X_i}{V_i}, \tag{3.6}$$

where $R_i \equiv D_i / V_i$ and $\mathbb{E}[D_i] = \mu_i$. Emission levels X_i govern the primitive cash-flow exposure in dividends, while expected returns load on the value-normalized exposure X_i / V_i. The coefficient λ is the equilibrium price of climate-related risk.

Solving for the price of climate risk Aggregating the definition of δ_h across households, multiplying by η, and imposing market clearing $\sum_{h=1}^{H} \theta_j^h = 1$ yields

$$\eta^2 \bar{X} \; - \; \kappa \eta \bar{X} \sum_{h=1}^{H} \phi_h \; = \; \eta \sum_{h=1}^{H} \delta_h. \tag{3.7}$$

Using (3.5), the right-hand side is $\eta \sum_{h=1}^{H} \delta_h = (\eta\lambda/\sigma_\zeta^2) \sum_{h=1}^{H} (1/\alpha_h)$. Solving for λ gives:

Proposition 2. *In the model above, the equilibrium price of climate risk is*

$$\lambda = \frac{\sigma_\zeta^2 \bar{X}}{\sum_{h=1}^{H} \frac{1}{\alpha_h}} \Big(\eta - \kappa \sum_{h=1}^{H} \phi_h \Big). \tag{3.8}$$

Proof is in Appendix A.1.

Under CARA preferences, λ depends on the distribution of risk aversion (α_h) and aggregate climate concern $\sum_h \phi_h$, and is independent of initial wealth (W_0^h).[3] Combining (3.8) with (3.6) shows how equilibrium expected returns reflect both the value-normalized exposure X_i/V_i and the aggregate price of climate risk λ, which depends on the distribution of risk aversion and climate concern across investors.

3.3 Decomposing transition risk and climate-concern hedging effects

The equilibrium price of climate risk admits a decomposition that separates compensation for bearing transition risk from a hedging component driven by heterogeneous concern about non-tradable climate damages. This decomposition isolates how market structure affects the price of risk, while the underlying exposure mapping remains governed by how shocks enter firms' cash flows.

Using (3.8), the price of climate risk in the incomplete-markets economy can be written as

$$\lambda_{X,t} = \frac{\sigma_\zeta^2 \bar{X}_t \eta}{\sum_{h=1}^{H} \frac{1}{\alpha_h}} - \frac{\sigma_\zeta^2 \bar{X}_t \kappa}{\sum_{h=1}^{H} \frac{1}{\alpha_h}} \sum_{h=1}^{H} \phi_h.$$

Define

$$\lambda_{X,t}^{\mathrm{TR}} \equiv \frac{\sigma_\zeta^2 \bar{X}_t \eta}{\sum_{h=1}^{H} \frac{1}{\alpha_h}}, \qquad \lambda_{X,t}^{\mathrm{H}} \equiv -\frac{\sigma_\zeta^2 \bar{X}_t \kappa}{\sum_{h=1}^{H} \frac{1}{\alpha_h}} \sum_{h=1}^{H} \phi_h, \tag{3.9}$$

so that

$$\lambda_{X,t} = \lambda_{X,t}^{\mathrm{TR}} + \lambda_{X,t}^{\mathrm{H}}. \tag{3.10}$$

In this representation, $\lambda_{X,t}$ denotes the equilibrium price per unit of emissions exposure $X_{i,t}$. Note that because dividend exposure to the climate shock is proportional to $\eta X_{i,t}$, the technology parameter η is absorbed into the transition-risk component $\lambda_{X,t}^{\mathrm{TR}}$ through the cash-flow loading,

[3] In Internet Appendix B, I show that with CRRA utility the analogous expression features wealth weights given by local risk tolerances.

while the hedging component $\lambda_{X,t}^{\mathrm{H}}$ reflects preference-driven demand for assets that covary with non-tradable climate damages and does not depend on firm-level technology.

The term $\lambda_{X,t}^{\mathrm{TR}}$ is the price of climate risk that would prevail if all households were climate-neutral, that is, if $\phi_h = 0$ for all h. It compensates investors for bearing unhedgeable exposure to the aggregate climate or policy shock ζ_{t+1} through the technological channel $D_{i,t+1} = \mu_{i,t+1} + \eta X_{i,t}\zeta_{t+1}$.

By contrast, $\lambda_{X,t}^{\mathrm{H}}$ arises from heterogeneous concern about non-tradable climate damages and is strictly decreasing in aggregate concern $\sum_h \phi_h$ when $\kappa > 0$. Differentiating (3.9) yields

$$\frac{\partial \lambda_{X,t}}{\partial \phi_h} = -\frac{\sigma_\zeta^2 \bar{X}_t \kappa}{\sum_{j=1}^{H} \frac{1}{\alpha_j}} < 0.$$

This comparative static reflects that assets with greater exposure to the climate shock provide a hedge against non-tradable climate damages, so stronger aggregate climate concern reduces the required compensation for holding such assets.

Given the decomposition (3.10), the expected excess return on firm i can be written as

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \lambda_{X,t}^{\mathrm{TR}} \frac{X_{i,t}}{V_{i,t}} + \lambda_{X,t}^{\mathrm{H}} \frac{X_{i,t}}{V_{i,t}}. \tag{3.11}$$

The first term reflects compensation for bearing non-diversifiable transition (or physical) climate risk, while the second term captures the pricing effect of hedging motives arising from heterogeneous climate concern.

An equivalent decomposition applies to the stochastic discount factor. Writing

$$m_{t+1} = \exp\big(-A_t - B_t \zeta_{t+1}\big), \qquad B_t = \frac{\lambda_{X,t}}{\sigma_\zeta^2},$$

we obtain

$$B_t = B_t^{\mathrm{TR}} + B_t^{\mathrm{H}},$$

with

$$B_t^{\mathrm{TR}} = \frac{\bar{X}_t \eta}{\sum_{h=1}^{H} \frac{1}{\alpha_h}}, \qquad B_t^{\mathrm{H}} = -\frac{\bar{X}_t \kappa}{\sum_{h=1}^{H} \frac{1}{\alpha_h}} \sum_{h=1}^{H} \phi_h.$$

The first component describes how the pricing kernel responds to the climate shock in the absence of climate concern, while the second captures the additional tilt induced by hedging demand.

Overall, this decomposition shows that transition risk and climate-concern hedging effects are conceptually distinct but jointly determine the observed carbon premium. The preference compo-

nent reflects hedging motives arising from non-tradable climate damages rather than direct preferences for holding green assets, although both channels may coexist in practice.

3.4 When is emission intensity a unique sufficient statistic?

The previous subsection shows that expected excess returns are governed by firms' factor exposures, which may depend on a rich set of characteristics $Z_{i,t}$. There is therefore no general reason why any single primitive, such as emission levels $X_{i,t}$ or emission intensity $X_{i,t}/V_{i,t}$, must be sufficient for climate-related pricing. This subsection formalizes and characterizes the knife-edge conditions under which emission intensity is a unique sufficient statistic for the priced exposure to a given climate or transition factor.

Definition 3.1 (Emission intensity as a sufficient statistic)**.** *Consider date t and a one-factor environment in which expected excess returns satisfy*

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \Lambda_t \chi_{i,t},$$

for some scalar Λ_t and some scalar characteristic $\chi_{i,t}$ that may depend on firm attributes. We say that emission intensity *is a sufficient statistic at date t if for any two firms i and j,*

$$\frac{X_{i,t}}{V_{i,t}} = \frac{X_{j,t}}{V_{j,t}} \quad \Rightarrow \quad \chi_{i,t} = \chi_{j,t}.$$

We say that intensity is a unique *sufficient statistic if, in addition, any other characteristic $\tilde{\chi}_{i,t}$ that generates an equivalent one-factor representation must be proportional to $X_{i,t}/V_{i,t}$ in the cross-section, that is, there exists a scalar ψ_t such that*

$$\tilde{\chi}_{i,t} = \psi_t \frac{X_{i,t}}{V_{i,t}} \quad \textit{for all } i.$$

One-factor environment and value normalization. For clarity, let us suppress time subscripts when no confusion arises. Let f_{t+1} denote a scalar transition or climate factor with $\mathbb{E}_t[f_{t+1}] = 0$, and consider dividends of the form

$$D_{i,t+1} = \mu_{i,t+1} + g(Z_{i,t}) f_{t+1}, \tag{3.12}$$

where $Z_{i,t}$ collects firm characteristics (including in particular $(X_{i,t}, V_{i,t})$), and $g(\cdot)$ is a deterministic function. The object $g(Z_{i,t})$ is a *cash-flow* exposure (in dividend units). Let the stochastic discount factor admit the linear projection representation

$$m_{t+1} = a_t + b_t f_{t+1} + \varepsilon_{t+1}, \tag{3.13}$$

with $a_t > 0$, b_t $\mathcal{F}_t$–measurable, and ε_{t+1} conditionally mean-zero and orthogonal to f_{t+1}. Using the Euler equation $\mathbb{E}_t[m_{t+1}R_{i,t+1}] = 1$ and the orthogonality of ε_{t+1}, expected excess returns satisfy

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \lambda_t \frac{g(Z_{i,t})}{V_{i,t}}, \qquad \lambda_t = -\frac{b_t \mathrm{Var}_t(f_{t+1})}{\mathbb{E}_t[m_{t+1}]}, \tag{3.14}$$

which follows directly from the covariance between firm returns and the pricing kernel. Market structure determines b_t and hence λ_t, but not the functional form of $g(\cdot)$.

Knife-edge conditions for intensity sufficiency. The next result characterizes when the return-relevant exposure $g(Z_{i,t})/V_{i,t}$ depends on firms only through emission intensity $X_{i,t}/V_{i,t}$, and when this dependence is unique up to scale. The result is model-agnostic and does not rely on the incomplete-markets structure developed earlier; it follows from the mapping between dollar cash-flow exposures and returns.

Proposition 3 (Conditions for emission intensity to be a unique sufficient statistic)**.** *Consider the one-factor environment* (3.12)-(3.14) *at a given date t. Suppose that:*

(i) The cross-section of firms is rich *in the sense that the set*

$$\mathcal{S}_t \equiv \left\{ \left(\frac{X_{i,t}}{V_{i,t}}, V_{i,t} \right) : i = 1, \ldots, N \right\}$$

exhibits independent variation in emission intensity and firm scale.[4]

(ii) The exposure function $g(\cdot)$ is homogeneous of degree one in $(X_{i,t}, V_{i,t})$ in the sense that, for all $\lambda > 0$ and all firms i,

$$g(Z_{i,t}; \lambda X_{i,t}, \lambda V_{i,t}) = \lambda\, g(Z_{i,t}; X_{i,t}, V_{i,t}).$$

[4]Formally, let $\mathcal{F}_t$ denote the limiting empirical distribution of $\left(\frac{X_{i,t}}{V_{i,t}}, V_{i,t}\right)$ as $N \to \infty$. Condition (i) requires that the support of $\mathcal{F}_t$ contains an open subset of $\mathbb{R}^2_+$, ruling out degenerate cases in which the cross-section of firms concentrates on a lower-dimensional manifold.

(iii) For any two firms i and j with the same intensity, $X_{i,t}/V_{i,t} = X_{j,t}/V_{j,t}$, their value-normalized exposures coincide,

$$\frac{g(Z_{i,t})}{V_{i,t}} = \frac{g(Z_{j,t})}{V_{j,t}}.$$

Then there exists a (measurable) function $\varphi_t : \mathbb{R}_+ \to \mathbb{R}$ such that

$$\frac{g(Z_{i,t})}{V_{i,t}} = \varphi_t\left(\frac{X_{i,t}}{V_{i,t}}\right) \quad \text{for all } i. \tag{3.15}$$

If, in addition, $g(\cdot)$ is continuous on $\mathcal{S}_t$ and the function $\varphi_t(\cdot)$ is linear in its argument, then there exists a scalar κ_t such that

$$\frac{g(Z_{i,t})}{V_{i,t}} = \kappa_t \frac{X_{i,t}}{V_{i,t}} \quad \text{for all } i, \tag{3.16}$$

and $X_{i,t}/V_{i,t}$ is a unique sufficient statistic for expected excess returns in the sense of Definition 3.1. Equivalently, (3.16) holds if and only if

$$g(Z_{i,t}) = \kappa_t X_{i,t} \quad \text{for all } i,$$

so that linear intensity sufficiency in returns corresponds to a level-proportional cash-flow exposure.

Proof is in Appendix A.1.

Proposition 3 makes explicit the identifying restrictions required for emission intensity to be uniquely sufficient in equilibrium. Two firms with the same ratio $X_{i,t}/V_{i,t}$ must have identical return-relevant exposure $g(Z_{i,t})/V_{i,t}$ regardless of their absolute scale, which requires both homogeneity of cash-flow exposures and scale invariance across firms. When these conditions fail, the exposure function $g(Z_{i,t})$ cannot be proportional to emissions alone, and additional characteristics beyond $X_{i,t}/V_{i,t}$ must enter priced exposure. Crucially, the restrictions have sharp empirical implications—spanning and scale invariance—that can be directly tested in the data.

More generally, the identification logic in Proposition 3 does not rely on emission intensity per se. The result reflects a broader property of asset pricing with value-normalized exposures. Expected returns are governed by the object $g(Z_{i,t})/V_{i,t}$, and any scalar characteristic that serves as a sufficient statistic for pricing must recover this object up to scale. In particular, if two characteristics both generate a valid one-factor representation of expected returns, they must be proportional in the cross section, as both are proportional to the same underlying exposure $g(Z_{i,t})/V_{i,t}$. Emis-

sion intensity therefore serves as a convenient and policy-relevant benchmark for illustrating the identification problem, but the underlying logic applies to any candidate measure of climate risk, including emission levels, changes, or composite ESG scores. The key question, however, is not which characteristic predicts returns, but whether a given characteristic recovers the relevant exposure function implied by the underlying economic mechanism.

The homogeneity and scale-invariance conditions are equivalent to requiring that the exposure function satisfies an additivity property under corporate reorganizations. Section 3.4 develops the economic foundations of these restrictions and identifies two distinct channels through which they fail in practice.

Notably, the analysis focuses on environments in which climate-related shocks enter firm cash flows in dollar terms, even when shocks are large or fat-tailed. If transition risk instead operates through survival or default-type thresholds that generate losses proportional to firm value, then the homogeneity and scale-invariance conditions required for intensity sufficiency may hold. In that case, emission intensity would naturally emerge as the relevant priced characteristic. My framework accommodates this regime as a boundary case; the empirical results indicate that it has not dominated pricing over the sample period studied.

Finally, the proposition also clarifies what does and does not hinge on market completeness. Completeness affects the equilibrium *price* of risk λ_t in (3.14), but it does not impose the scale and homogeneity restrictions on $g(\cdot)$ needed for intensity sufficiency. These implications motivate the empirical sufficiency tests in Section 6.2, which evaluate the scale-invariance and spanning restrictions associated with Proposition 3.

Economic foundations of the sufficiency conditions Proposition 3 shows that emission intensity is a sufficient statistic for priced exposure only when the exposure function $g(\cdot)$ is homogeneous of degree one in $(X_{i,t}, V_{i,t})$ and satisfies scale invariance. These are mathematical restrictions on the exposure function. This subsection provides their economic interpretation and explains why they are unlikely to hold in general.

The key economic property underlying homogeneity is *additivity* of exposure. Consider a firm with emissions $X_{i,t}$ and value $V_{i,t}$ that is split into n identical entities, each with emissions $X_{i,t}/n$ and value $V_{i,t}/n$. Additivity requires that the total dollar cash-flow exposure to the climate shock be preserved:

$$n \cdot g\left(\frac{X_{i,t}}{n}, \frac{V_{i,t}}{n}, Z_{-X,V}\right) = g(X_{i,t}, V_{i,t}, Z_{-X,V})\,, \tag{3.17}$$

where $Z_{-X,V}$ collects all other firm characteristics held fixed in the partition experiment.

To see why additivity implies homogeneity of degree one, consider two operations. First, splitting a firm into n identical entities implies

$$g\left(\frac{X_{i,t}}{n}, \frac{V_{i,t}}{n}\right) = \frac{g(X_{i,t}, V_{i,t})}{n}.$$

Second, merging n identical firms with emissions X and value V into a single firm with emissions nX and value nV implies

$$g(nX, nV) = ng(X, V).$$

Together, these operations yield $g(\lambda X, \lambda V) = \lambda g(X, V)$ for all positive rational λ. Under continuity, the relation extends to all $\lambda > 0$, establishing homogeneity of degree one in $(X_{i,t}, V_{i,t})$. Consequently, value-normalized exposure $g(Z_{i,t})/V_{i,t}$ depends on firm characteristics only through emission intensity $X_{i,t}/V_{i,t}$.

Additivity holds when climate shocks translate into cash-flow impacts that are mechanically proportional to emissions and independent of firm scale. A uniform carbon tax is the canonical example: a change $\Delta\tau$ generates a compliance cost $\Delta\tau\, X_{i,t}$, and splitting the firm preserves total exposure. This structure is also implicit in sustainable-discount-rate representations, in which expected returns take the form $r^x_{i,t} \approx r_t + (S_t - \tau_t)X_{i,t}/V_{i,t}$. In this case, the underlying exposure is $g(Z_{i,t}) = \eta X_{i,t}$, which satisfies additivity by construction.

This property can fail through two economically distinct channels. First, many real-world climate policies do not operate on a per-ton basis. Regulatory thresholds, disclosure rules, and benchmark-based allocations often create fixed or level-based compliance costs that depend on absolute scale rather than proportional emissions. For example, firms above regulatory cutoffs must purchase allowances or install monitoring infrastructure, while smaller firms may avoid these costs even when aggregate emissions are unchanged. Similarly, net-zero benchmarks are typically allocated using sectoral budgets, installed capacity, or historical baselines rather than firm value, so two firms with identical emission intensity but different scale can face very different compliance gaps. In such settings, corporate structure affects total exposure and additivity fails at the level of the policy instrument.

Second, additivity can fail even under a perfectly uniform carbon tax. While the policy shock is linear per ton, its cash-flow impact depends on firms' pricing power, input substitution possibilities, contractual structure, and adjustment costs. Firms differ in their ability to pass carbon

costs through to output prices, implying that identical emissions can translate into very different cash-flow effects. Because these pass-through rates vary systematically with market structure and technology, the mapping from carbon price shocks to cash flows is generically firm-specific and scale-dependent. Achieving additivity therefore requires not only a per-unit instrument but also homogeneous economic incidence across firms.

Together, these arguments imply that the homogeneity and scale-invariance restrictions require a joint set of conditions: climate exposure must operate through per-unit instruments, the incidence of those instruments must be homogeneous across firms, and regulation must avoid thresholds, benchmarks, or trajectory-based constraints. These conditions are restrictive. Relaxing any one of them causes exposure to depend on firm characteristics beyond emission intensity.

More broadly, the exposure function $g(Z_{i,t})$ is generically multidimensional. Emissions determine the direct incidence of per-unit policy shocks, but the cash-flow impact of a given shock is mediated by firm-specific characteristics—pricing power, demand elasticity, contractual rigidity, input substitution, and adjustment costs—that are not summarized by any single emission metric. The corresponding single-statistic benchmark, in which $g(Z_{i,t}) = \eta X_{i,t}$, should therefore be viewed as a tractable specification that isolates the direct policy channel by shutting down mediating heterogeneity, rather than as a description of the typical firm environment.

This logic applies symmetrically to any candidate emission characteristic, not only to intensity. Firms with identical emissions, identical intensity, and identical policy exposure can nevertheless have different cash-flow sensitivities to climate shocks when incidence is heterogeneous. Identifying the full exposure function $g(Z_{i,t})$—incorporating incidence heterogeneity, pass-through, and technology—remains an open structural question to which this paper's selection framework provides the analytical foundation.

4 Climate Risk, Emission Intensity, and Priced Characteristics

In this section I embed emission-based climate metrics in a general linear-factor pricing framework. The key distinction is between (i) cash-flow exposures $g_k(Z_{i,t})$, which describe how climate-related shocks enter dividends, and (ii) return exposures, which are value-normalized and therefore load on $g_k(Z_{i,t})/V_{i,t}$. The central question is thus when the value-normalized exposure can be summarized by emission intensity $X_{i,t}/V_{i,t}$ alone. Proposition 3 characterizes the knife-edge conditions for a one-factor environment. The remainder of this section extends the representation to multiple factors

and characterizes the implications for emission-based measures of climate risk.[5]

4.1 Climate-related risk as stochastic exposure to policy or technology shocks

Consider climate-related risk, with transition risk as a leading example, defined as stochastic shocks to climate policy, carbon prices, or technology that affect firms' cash flows. To fix ideas, let τ_{t+1} denote a random carbon price at date $t+1$ and suppose that, holding quantities fixed at date t, firm i's date-$t+1$ dividend contains a term

$$D_{i,t+1} = \tilde{D}_{i,t+1} - \tau_{t+1} X_{i,t}, \tag{4.1}$$

where $\tilde{D}_{i,t+1}$ collects all other components orthogonal (conditionally) to $\hat{\tau}_{t+1}$. Let $\hat{\tau}_{t+1} \equiv \tau_{t+1} - \mathbb{E}_t[\tau_{t+1}]$ denote the innovation in the carbon price and write

$$D_{i,t+1} = \mu_{i,t+1} + g_{i,t}^{(\tau)} \hat{\tau}_{t+1}, \qquad g_{i,t}^{(\tau)} = -X_{i,t},$$

with $\mu_{i,t+1}$ conditionally mean-independent of $\hat{\tau}_{t+1}$. In any equilibrium, expected excess returns satisfy

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = -\frac{\mathrm{Cov}_t(m_{t+1}, D_{i,t+1})}{\mathbb{E}_t[m_{t+1}]\, V_{i,t}},$$

where $V_{i,t}$ denotes the date-t market value (price) of the claim to $D_{i,t+1}$. Substituting the dividend representation into the covariance pricing identity yields

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \lambda_t^{(\tau)} \frac{g_{i,t}^{(\tau)}}{V_{i,t}} = -\lambda_t^{(\tau)} \frac{X_{i,t}}{V_{i,t}}, \tag{4.2}$$

where the price of transition risk associated with carbon-price shocks is defined by

$$\lambda_t^{(\tau)} = -\frac{\mathrm{Cov}_t(m_{t+1}, \hat{\tau}_{t+1})}{\mathbb{E}_t[m_{t+1}]}.$$

In the special case of a carbon-price shock with linear incidence, exposure is proportional to emissions, but in general the exposure functions $g_k(Z_{i,t})$ need not collapse to any single emission-based measure.

[5] I now adopt time subscripts. All static results in Sections 2-3 carry over to the dynamic setting under standard CARA-normal assumptions (see Internet Appendix D).

More generally, allowing for multiple climate-related channels, dividends take the form

$$D_{i,t+1} = \tilde{D}_{i,t+1} + \sum_{k=1}^{K} g_k(Z_{i,t}) f_{k,t+1}, \tag{4.3}$$

where $f_{k,t+1}$ are mean-zero climate-related factors (e.g., policy, technology, or demand shocks) and $g_k(Z_{i,t})$ are dollar exposure coefficients that depend on characteristics $Z_{i,t}$, which may include $X_{i,t}$, $V_{i,t}$, $X_{i,t}/V_{i,t}$, changes in emissions, efficiency measures, and so on. Asset pricing maps dollar exposures into return premia via normalization by firm value, so the relevant objects are $g_k(Z_{i,t})/V_{i,t}$.

4.2 Market completeness, prices of risk, and exposure functions

Building on this distinction, this subsection examines how market completeness affects equilibrium pricing. Complete versus incomplete markets affect the prices of climate-related risk but not, for a given technology and shock structure, the mechanism-implied dollar exposure functions $g_k(Z_{i,t})$. To make this precise, consider the following general linear-factor environment.

Let $\{f_{k,t+1}\}_{k=1}^{K}$ be conditionally mean-zero factors, and suppose that dividends satisfy (4.3):

$$D_{i,t+1} = \mu_{i,t+1} + \sum_{k=1}^{K} g_k(Z_{i,t}) f_{k,t+1},$$

with $\mu_{i,t+1}$ conditionally independent of $\{f_{k,t+1}\}_k$ and $Z_{i,t}$ $\mathcal{F}_t$–measurable. Assume that the stochastic discount factor admits the linear projection representation

$$m_{t+1} = a_t + \sum_{k=1}^{K} b_{k,t} f_{k,t+1} + \varepsilon_{t+1}, \tag{4.4}$$

where $a_t > 0$, $\{b_{k,t}\}_k$ are $\mathcal{F}_t$–measurable, and ε_{t+1} is conditionally mean-zero and orthogonal to all factors and traded payoffs. Under complete markets, the SDF is unique and coincides with the representative agent's or planner's marginal rate of substitution. Under incomplete markets, the SDF is not unique in general, but any admissible SDF admits a representation of the form (4.4), and in our CARA-normal environment equilibrium pins down a particular affine specification.

Using the Euler equation $\mathbb{E}_t[m_{t+1}R_{i,t+1}] = 1$ together with (4.3) and (4.4) yields the following characterization.

Proposition 4 (Priced characteristics in a linear factor structure)**.** *Suppose that dividends are given by* (4.3) *and that the SDF admits the representation* (4.4)*, with* $\{f_{k,t+1}\}_k$ *mutually uncorrelated*

conditional on $\mathcal{F}_t$. Then expected excess returns satisfy

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \sum_{k=1}^{K} \lambda_{k,t} \frac{g_k(Z_{i,t})}{V_{i,t}}, \tag{4.5}$$

where

$$\lambda_{k,t} = -\frac{b_{k,t} \operatorname{Var}_t(f_{k,t+1})}{\mathbb{E}_t[m_{t+1}]}, \qquad k = 1, \dots, K, \tag{4.6}$$

are the factor prices of risk. In particular, for each factor k, the priced return exposure is the value-normalized object $g_k(Z_{i,t})/V_{i,t}$: two assets with identical value-normalized exposures for all k have identical expected excess returns, regardless of how $g_k(\cdot)$ depends on primitives such as $(X_{i,t}, V_{i,t}, \dots)$.

Proof. Substituting (4.3) and (4.4) into the covariance pricing identity

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = -\frac{\operatorname{Cov}_t(m_{t+1}, D_{i,t+1})}{\mathbb{E}_t[m_{t+1}]\, V_{i,t}}$$

and using orthogonality of ε_{t+1} and conditional mutual uncorrelatedness of the factors yields

$$\operatorname{Cov}_t(m_{t+1}, D_{i,t+1}) = \sum_{k=1}^{K} b_{k,t}\, g_k(Z_{i,t}) \operatorname{Var}_t(f_{k,t+1}),$$

which implies (4.5) and (4.6). □

Proposition 4 holds irrespective of whether markets are complete or incomplete. Market completeness affects the equilibrium coefficients $\{b_{k,t}\}_k$ and thus the prices of risk $\{\lambda_{k,t}\}_k$, but not the functional form of the exposure coefficients $g_k(Z_{i,t})$.

The separation between market structure and the exposure function $g_k(\cdot)$ is exact when firm characteristics are taken as predetermined at date t. In richer general-equilibrium environments, firms may adjust emissions, technology, or production in response to expected policy and risk premia. In such settings, the equilibrium mapping $g_k(Z_{i,t})$ can itself depend on the price of risk through firms' optimal decisions. Proposition 4 should therefore be interpreted as characterizing the pricing of exposures conditional on the characteristics realized at date t. The dynamic production model in Appendix D provides an example in which exposures are endogenous, yet the value-normalized representation (4.5) continues to describe the cross section of expected returns.

In the transition-tax example (4.1) with a single factor $f_{1,t+1} = \hat{\tau}_{t+1}$, Proposition 4 identifies $g_1(Z_{i,t})$ with $-X_{i,t}$ and thus the priced return exposure with $-X_{i,t}/V_{i,t}$. More generally, when

$g_k(Z_{i,t})$ depends on emission levels, changes, technology, or policy allocations, the resulting priced characteristics are the corresponding value-normalized exposure functions $g_k(Z_{i,t})/V_{i,t}$. There is therefore no general reason to expect that a single statistic such as emission intensity $X_{i,t}/V_{i,t}$ will be sufficient to summarize transition exposure across models. The next section illustrates how alternative, economically motivated specifications of $g_k(\cdot)$ generate premia on emission levels, intensity, and changes through these exposure functions.

5 Illustrative Exposure Specifications

Section 3.4 showed that emission intensity is a sufficient statistic only under economically demanding homogeneity and scale-invariance restrictions. The goal of this section is complementary. Rather than asking when intensity is sufficient, I now construct exposure functions implied by concrete policy and technology mechanisms and derive the priced characteristics they generate. The incomplete-markets equilibrium in Section 3 relied on a simple benchmark in which dividends load linearly on emission levels. Realistic climate exposure, however, is richer. Policy shocks need not scale only with current emissions: they can depend on recent changes, distances from regulatory benchmarks, and technology choices that reshape how cash flows respond to climate risk. The analysis below therefore derives exposure functions directly from economically motivated mechanisms. The three specifications that follow–transition losses proportional to levels (the Section 3 benchmark), exposures depending jointly on levels and changes (motivated by trajectory-based regulation), and path-based exposures under net-zero commitments–illustrate a general lesson. Once exposure functions are disciplined by realistic policy design and technology, the priced characteristics that enter equilibrium returns need not collapse to emission intensity.

5.1 Exposure proportional to emission levels

I start with the simplest case: cash-flow exposure proportional to emission levels. For example, if a per-ton carbon price increases by \$10 and a firm emits 100 kilotons, its compliance cost rises by \$1 million. A reduced-form representation of this channel is $\theta_{i,t} = \eta X_{i,t}$, linear in emissions.[6] This specification is natural when policy operates through per-unit instruments–carbon taxes, permit obligations, or output restrictions that scale directly with total emissions.

Asset pricing converts dollar cash-flow exposure into a return premium by dividing by firm

[6] To streamline notation, I denote the dollar exposure to the climate factor by $\theta_{i,t}$.

value. Under $\theta_{i,t} = \eta X_{i,t}$, the priced exposure is therefore $\eta X_{i,t}/V_{i,t}$, so emission intensity emerges mechanically as a sufficient statistic for pricing. The key point, however, is that this sufficiency is not a generic implication of equilibrium pricing: it holds here only because the primitive cash-flow channel is linear in levels and does not depend on other scale objects. Once exposure depends on additional characteristics such as changes in emissions, compliance constraints, or distance from a regulatory path, two firms with the same $X_{i,t}/V_{i,t}$ can have different $g(Z_{i,t})/V_{i,t}$, and intensity no longer spans priced exposure.

Single-factor setup. To formalize this, consider a single climate factor ζ_{t+1} with $\mathbb{E}_t[\zeta_{t+1}] = 0$ and write firm i's dividend as

$$D_{i,t+1} = \tilde{D}_{i,t+1} + \theta_{i,t}\,\zeta_{t+1}, \tag{5.1}$$

where $\tilde{D}_{i,t+1}$ is orthogonal to ζ_{t+1}. The cash-flow exposure $\theta_{i,t}$ depends on firm characteristics $Z_{i,t}$ through

$$\theta_{i,t} = g(Z_{i,t}), \tag{5.2}$$

where $g : \mathcal{Z} \to \mathbb{R}$ maps characteristics–emissions, firm value, technology shifters, policy allocations–into dollar sensitivities. In the Section 3 benchmark, $Z_{i,t} = X_{i,t}$ and $g(z) = \eta z$, so $\theta_{i,t} = \eta X_{i,t}$.

Under the linear factor representation in Proposition 4, expected excess returns satisfy

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \lambda_t \frac{g(Z_{i,t})}{V_{i,t}}, \tag{5.3}$$

where λ_t is the equilibrium price of factor risk. The priced object is the value-normalized exposure $g(Z_{i,t})/V_{i,t}$.

From mechanisms to empirical predictors. The functional form of $g(\cdot)$ is disciplined by economic structure: it reflects how climate shocks enter cash flows. If $g(Z_{i,t}) = \eta X_{i,t}$, equation (5.3) delivers

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \lambda_t \eta \frac{X_{i,t}}{V_{i,t}},$$

so emission intensity becomes the return exposure even though the primitive cash-flow channel scales with levels. But if policy operates through adjustment costs, compliance constraints, or net-zero benchmarks, $g(Z_{i,t})$ naturally depends on additional characteristics–emission changes $\Delta X_{i,t}$, compliance constraints, and distances from regulatory paths or net-zero benchmarks. The priced

return exposure remains $g(Z_{i,t})/V_{i,t}$, but this object need not collapse to intensity.

The theory thus disciplines measurement: an emission-based predictor is admissible only if it can be derived from a coherent cash-flow mechanism, and it is empirically sufficient if it spans the return variation associated with $g(Z_{i,t})/V_{i,t}$. Intensity is sufficient only when dollar exposures satisfy the homogeneity and scale-invariance conditions in Proposition 3–conditions that fail once $g(\cdot)$ depends on characteristics beyond $(X_{i,t}, V_{i,t})$.

Multi-factor extension. With multiple climate shocks $\boldsymbol{\zeta}_{t+1} = (\zeta_{1,t+1}, \ldots, \zeta_{K,t+1})^\top$, dividends become

$$D_{i,t+1} = \tilde{D}_{i,t+1} + \sum_{k=1}^{K} \theta_{i,t}^{(k)} \zeta_{k,t+1}, \qquad \theta_{i,t}^{(k)} = g_k(Z_{i,t}),$$

and expected returns inherit the structure

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \sum_{k=1}^{K} \lambda_t^{(k)} \frac{g_k(Z_{i,t})}{V_{i,t}}. \tag{5.4}$$

Each factor $\zeta_{k,t+1}$ is priced through its exposure function $g_k(Z_{i,t})/V_{i,t}$. Physical damage shocks, carbon-price innovations, and technology shocks can each generate distinct exposure functions, and there is no reason to expect a single characteristic such as intensity to span all of them.

Invariance restrictions on exposure functions. Not every function $g(\cdot)$ is economically coherent. Dollar exposures must satisfy basic invariance requirements. Splitting a firm into two identical copies with half the emissions and half the value should preserve total exposure (additivity). Holding technology fixed, higher emissions should not reduce exposure to a per-unit tax or damage shock (monotonicity). These restrictions ensure that exposure functions correspond to actual economic mechanisms rather than arbitrary functional forms.

Under these disciplines, emission levels, intensities, changes, and SCC-weighted measures are all admissible–each can be derived from a specific policy or technology channel. But they are empirically sufficient only if they span the priced exposure $g_k(Z_{i,t})/V_{i,t}$. When cash flows depend on characteristics beyond those captured by a given metric, that metric fails the spanning tests in Section 6.2.

5.2 Transition losses depending on levels and changes

Policy tightening doesn't just penalize current emissions–it targets firms moving in the wrong direction. A coal plant ramping up capacity faces different regulatory risk than one phasing down, even if both have similar emission levels today. If enforcement responds to trajectories rather than stocks, cash-flow exposure depends on both $X_{i,t}$ and $\Delta X_{i,t}$, and intensity alone cannot span the priced risk.

To see this, consider a policy shock that arrives when regulators perceive insufficient progress toward transition goals. Firms increasing emissions signal resistance to decarbonization and face steeper penalties when enforcement tightens. Formally, let transition losses depend on both the current emission stock and recent changes:

$$\Gamma_{i,t} = \phi_1 X_{i,t} + \phi_2 \Delta X_{i,t}, \tag{5.5}$$

where $\Delta X_{i,t} = X_{i,t} - X_{i,t-1}$ and $\phi_1, \phi_2 > 0$. The level $X_{i,t}$ captures baseline exposure; the change $\Delta X_{i,t}$ captures trajectory risk.

Policy-tightening shocks and transition losses. Let $J_{t+1} \in \{0, 1\}$ denote a binary tightening event with $\mathbb{E}_t[J_{t+1}] = p_t$, and define the innovation

$$\zeta_{t+1} = J_{t+1} - p_t.$$

The shock J_{t+1} captures unanticipated regulatory acceleration–stricter enforcement, faster phase-outs, or abrupt carbon-price increases. Firm i's dividend becomes

$$D_{i,t+1} = \bar{D}_{i,t+1} - \Gamma_{i,t} J_{t+1}, \tag{5.6}$$

where $\bar{D}_{i,t+1}$ is the dividend absent tightening and $\Gamma_{i,t}$ is the dollar loss when tightening occurs. This loss reflects stranded assets, accelerated abatement costs, or compliance penalties that hit when policy shifts earlier than expected.

Substituting (5.5) into (5.6) and using $\zeta_{t+1} = J_{t+1} - p_t$ yields

$$D_{i,t+1} = \bar{D}_{i,t+1} - (\phi_1 X_{i,t} + \phi_2 \Delta X_{i,t}) p_t - (\phi_1 X_{i,t} + \phi_2 \Delta X_{i,t}) \zeta_{t+1}.$$

The cash-flow exposure to the transition factor is

$$g_\zeta(Z_{i,t}) = -(\phi_1 X_{i,t} + \phi_2 \Delta X_{i,t}),$$

where $Z_{i,t}$ includes both levels and changes.

Equilibrium pricing with trajectory dependence. Under the log-linear approximation in Proposition 4, expected excess returns satisfy

$$\mathbb{E}_t[R_{i,t+1} - R_{f,t}] = \lambda_{\zeta,t} \frac{\phi_1 X_{i,t} + \phi_2 \Delta X_{i,t}}{V_{i,t}} + \text{other factor terms.} \tag{5.7}$$

Both levels and changes enter through the value-normalized exposure $(\phi_1 X_{i,t} + \phi_2 \Delta X_{i,t})/V_{i,t}$. When $\phi_2 = 0$, the model collapses to the Section 5.1 baseline where exposure scales with levels alone. When $\phi_2 > 0$, firms ramping up emissions bear additional transition risk that cannot be captured by $X_{i,t}/V_{i,t}$ alone.

This has direct implications for intensity-based screens. Two firms with identical emission intensity can have different priced exposure if one is increasing emissions ($\Delta X_{i,t} > 0$) while the other is cutting ($\Delta X_{i,t} < 0$). The sufficiency conditions in Proposition 3 fail because the exposure function depends on an additional characteristic–recent emission changes–that is not summarized by the intensity ratio $X_{i,t}/V_{i,t}$.

Empirical implications. Equation (5.7) suggests that the appropriate empirical specification includes both $X_{i,t}/V_{i,t}$ and $\Delta X_{i,t}/V_{i,t}$ as predictors. A regression of returns on these characteristics is a reduced-form test of whether trajectory-based exposure is priced. The coefficients need not recover (ϕ_1, ϕ_2) separately, as they combine technological sensitivities with the equilibrium price of risk $\lambda_{\zeta,t}$, but the joint specification is the natural empirical analogue of the mechanism in (5.5).

The incomplete-markets structure, heterogeneous climate concern, and SDF decomposition from Section 3 remain unchanged. What changes is the exposure function $g_\zeta(Z_{i,t})$, which now depends on both stocks and flows. This illustrates the general point: different policy designs generate different priced characteristics, and intensity suffices only under the knife-edge restriction that exposure depends solely on $(X_{i,t}, V_{i,t})$.

5.3 Net-zero objectives and path-based exposure

Net-zero commitments change the regulatory game. A firm emitting 150 kilotons with a 100-kiloton benchmark faces different transition risk than a firm at 75 kilotons with a 50-kiloton benchmark–even though both are 50% above their targets. What matters is not just the intensity ratio but the absolute distance from a mandated path, and that distance varies with scale even when $X_{i,t}/V_{i,t}$ is fixed.

This matters because net-zero benchmarks are typically allocated using level-based rules–sectoral budgets, capacity shares, historical baselines–not intensity targets. Two firms with identical emission intensity can have vastly different compliance trajectories if one is large and distant from its benchmark while the other is small and close. If enforcement tightens or phase-out schedules accelerate, exposure scales with the gap $(X_{i,t} - X_{i,t}^{NZ})$, not just with current emissions or their ratio to firm value. Because $X_{i,t}^{NZ}$ is not proportional to $V_{i,t}$ under level-based allocations, the normalized gap $(X_{i,t} - X_{i,t}^{NZ})/V_{i,t}$ varies across firms even when $X_{i,t}/V_{i,t}$ is held fixed. Intensity alone therefore cannot span priced exposure in (5.9).

Path-based exposure under net-zero regulation. Let $X_{i,t}^{NZ}$ denote firm i's net-zero-consistent benchmark at date t, constructed from sectoral pathways, regulatory allocations, or firm commitments. This benchmark is predetermined at t and reflects policy design or historical negotiations rather than equilibrium outcomes; it may be measured with error in practice. Let ζ_{t+1} denote net-zero transition news: an acceleration of phase-out schedules, stricter enforcement, or increases in marginal abatement costs along the transition path.

Cash-flow exposure to ζ_{t+1} reflects two channels. First, per-unit losses that scale with current emissions $X_{i,t}$ (permit obligations, tax exposure). Second, repricing and compliance risk tied to the distance from the benchmark, $(X_{i,t} - X_{i,t}^{NZ})$. Formally, let

$$g_\zeta(Z_{i,t}) = \vartheta_1 X_{i,t} + \vartheta_2 (X_{i,t} - X_{i,t}^{NZ}), \tag{5.8}$$

where $\vartheta_1, \vartheta_2 \geq 0$. The level $X_{i,t}$ captures baseline exposure, while the gap $(X_{i,t} - X_{i,t}^{NZ})$ captures path-deviation risk under net-zero regulation.[7]

[7] One can additionally allow adjustment-speed penalties proportional to $\Delta X_{i,t}$ as in Section 5.2.

Equilibrium pricing with path dependence. Under the log-linear approximation in Proposition 4, expected excess returns satisfy

$$\mathbb{E}_t[R_{i,t+1} - R_{f,t}] = \lambda_{\zeta,t} \frac{g_\zeta(Z_{i,t})}{V_{i,t}} + \text{other factor terms.} \tag{5.9}$$

The priced exposure is the value-normalized function

$$\frac{g_\zeta(Z_{i,t})}{V_{i,t}} = \vartheta_1 \frac{X_{i,t}}{V_{i,t}} + \vartheta_2 \frac{X_{i,t} - X_{i,t}^{NZ}}{V_{i,t}}.$$

Intensity $X_{i,t}/V_{i,t}$ alone cannot span this exposure. Even firms with identical intensity can have sharply different path deviations $(X_{i,t} - X_{i,t}^{NZ})/V_{i,t}$ because benchmarks are allocated by levels or capacity shares, not intensity ratios. A large firm at 100% above its benchmark carries fundamentally different compliance risk than a small firm at 100% above its benchmark—the absolute emission gap that must be closed differs by scale.

The sufficiency conditions in Proposition 3 require that priced exposure depend only on $(X_{i,t}, V_{i,t})$ and satisfy homogeneity and scale invariance. Net-zero exposures violate these conditions in two ways. First, they depend on an additional predetermined characteristic, $X_{i,t}^{NZ}$, that reflects policy design rather than current firm decisions. Second, because benchmarks are level-based, the gap $(X_{i,t} - X_{i,t}^{NZ})/V_{i,t}$ varies with scale even when intensity is fixed. Consequently, intensity-based screens systematically misclassify firms when compliance risk is path-dependent.

Equation (5.9) suggests that empirical specifications motivated by path-based regulation include not only $X_{i,t}/V_{i,t}$ but also the normalized deviation $(X_{i,t} - X_{i,t}^{NZ})/V_{i,t}$. A spanning test that includes only intensity implicitly imposes $\vartheta_2 = 0$, that is, that transition risk is insensitive to distance from the benchmark. This restriction is economically strong in settings where compliance is assessed relative to net-zero pathways rather than current flow emissions alone.

Net-zero objectives thus provide a concrete illustration of the paper's central message: the appropriate emission-based predictor is determined by policy design, not by intensity a priori. When regulation operates through path constraints, the priced characteristic is the exposure function $g_\zeta(Z_{i,t})/V_{i,t}$, which depends on levels, gaps, and changes jointly. Intensity sufficiency is a knife-edge special case that holds only when transition risk ignores path deviations and adjustment dynamics—conditions unlikely to hold in environments where cumulative emissions or trajectory compliance drives enforcement.

To conclude this section, Table 1 summarizes the model's implications for empirical implemen-

tation. For each economic mechanism, formalized through an exposure function $g(Z_{i,t})$, the table reports the object that prices equilibrium returns and the corresponding variable implied for return regressions. The table serves as a compact reference, abstracting from regression controls and normalization that are common across specifications.

6 Empirical Implications

In this section I implement the sufficiency tests implied by Proposition 3 for emission intensity, the leading policy-relevant candidate. Importantly, the goal is not to determine which characteristic delivers the strongest return predictability. Instead, the tests evaluate the two knife-edge restrictions that must hold if emission intensity is a sufficient statistic for priced climate exposure. First, the spanning restriction implies that intensity should capture the cross-section of expected returns once emission levels are included. Second, the scale-invariance restriction implies that the pricing of intensity should not vary systematically with firm size. Rejection of either restriction is sufficient to reject intensity sufficiency. The empirical results below evaluate both restrictions directly.

The preceding analysis implies that emission intensity summarizes priced climate risk only under restrictive conditions on the underlying exposure function. In general, expected returns depend on value-normalized exposures $g(Z_{i,t})$, which need not collapse to emission intensity. This insight guides the empirical design. Rather than asking which characteristic predicts returns, I test whether the restrictions required for intensity sufficiency are supported by the data. These tests are not tests of market completeness per se. Market completeness affects the equilibrium price of risk λ_t, but emission intensity can be a sufficient statistic only if the exposure function $g(\cdot)$ satisfies the homogeneity and scale-invariance restrictions derived in Proposition 3. The analysis below evaluates these restrictions directly using an international panel of firms.

6.1 Interpreting Intensity-Based Measures

The framework developed in Sections 2-4 implies that emission intensity can play different roles depending on the underlying exposure function. In general, expected returns are determined by value-normalized exposure functions $g_k(Z_{i,t})/V_{i,t}$, where the functional forms of the $g_k(\cdot)$ depend on how climate and policy shocks enter firms' cash flows.

Emission intensity $X_{i,t}/V_{i,t}$ is a sufficient statistic for pricing only under restrictive conditions. Proposition 3 shows that exposure functions must be homogeneous of degree one in $(X_{i,t}, V_{i,t})$

and satisfy scale invariance, so that firms with the same intensity carry identical priced exposure regardless of size. These conditions impose sharp cross-sectional restrictions that can be tested directly in the data.

The empirical analysis below evaluates these restrictions. Rather than interpreting return predictability as evidence for a particular reduced-form proxy, the tests assess whether emission intensity captures the underlying exposure function that governs equilibrium risk premia.

Welfare implications of market incompleteness. Carbon premia reflect second-best equilibrium prices of transition exposure, not normative welfare wedges. Welfare comparisons require an explicit planner benchmark with a well-defined social cost of carbon and cannot be inferred from observed premia alone. Internet Appendix C formalizes the consumption-equivalent welfare loss from incomplete markets and shows it decomposes into risk-sharing and internalization components.

Why this matters for empirical work. The distinction is not merely conceptual—it has direct implications for how we interpret carbon premia in asset prices. Intensity-based approaches implicitly assume that equilibrium exposure functions satisfy the homogeneity and scale-invariance conditions required for intensity sufficiency. When these structural conditions fail, equilibrium pricing need not collapse to a function of $X_{i,t}/V_{i,t}$ alone. Instead, priced characteristics reflect the underlying exposure functions determined by technology, regulation, and firm behavior. Section 5 shows that these functions may depend on emission levels (when per-unit policies scale cash-flow losses with $X_{i,t}$), emission changes (when regulation responds to trajectories), net-zero gaps (when compliance is path-dependent), or efficiency choices (when technology affects shock sensitivity).

The conflicting findings in the empirical literature—with some studies documenting premia on levels, others on intensity, and still others on changes or composite scores—reflect this deeper economic point. Different emission metrics capture different exposure channels, and no single metric is universally sufficient. Rather, the appropriate predictor depends on which economic mechanisms govern the mapping from firm characteristics into priced cash-flow exposure.

More fundamentally, multifactor pricing does not imply that emission intensity must be one of the priced characteristics. Whether intensity enters equilibrium pricing depends on the microfoundations of how climate and policy shocks enter cash flows; in many economically relevant environments, priced exposure depends on emission levels, trajectories, net-zero gaps, or other firm characteristics beyond intensity.

Testable implications. Proposition 3 translates the sufficiency conditions into two empirical restrictions. First, *scale invariance*: if intensity is sufficient, the premium per unit of $X_{i,t}/V_{i,t}$

must not vary with firm size (Table 3). Second, *spanning*: conditional on intensity, emission levels should carry no incremental explanatory power for expected returns (Tables 4 and 5). These tests discipline the interpretation of intensity-based metrics by evaluating whether intensity summarizes equilibrium pricing or instead reflects only one component of a richer exposure structure.

The empirical strategy below tests both restrictions directly. The goal is not to advocate for levels over intensity, but to assess whether the structural conditions required for intensity sufficiency hold in the data. Rejection of these conditions clarifies that the debate in the literature reflects distinct economic questions–optimal policy implementation versus equilibrium risk measurement–rather than competing choices among observationally equivalent metrics.

6.2 Empirical evidence on sufficiency

I now test both restrictions using an international panel of firms. The contribution of the empirical analysis is not to estimate the magnitude of a carbon premium per se, but to evaluate the cross-sectional restrictions implied by the theory. First, *scale invariance*: if priced transition exposure depends only on $X_{i,t}/V_{i,t}$, then the premium per unit of intensity must be invariant to firm scale. Second, *spanning*: if intensity is sufficient, it must span emission levels in return regressions, so that conditional on $X_{i,t}/V_{i,t}$, emission levels $X_{i,t}$ carry no incremental explanatory power.

Under the equilibrium pricing framework developed in Section 3, cross-sectional differences in expected returns arise from differences in value-normalized exposure functions $g(Z_{i,t})/V_{i,t}$. Because firm characteristics such as emissions and intensity are predetermined with respect to subsequent shocks, predictable return differences associated with these characteristics provide reduced-form evidence on the underlying equilibrium exposure functions. The regressions below therefore test whether emission intensity alone summarizes the priced exposure or whether additional scale-dependent components are required.

I implement a direct test of scale invariance by allowing the intensity premium to vary across size bins and testing the implied cross-bin equality restriction. I then conduct asymmetric spanning tests that distinguish whether intensity subsumes levels or, conversely, whether levels subsume intensity. Finally, I report within-size-bin spanning tests that address the concern that pooled results reflect residual slope heterogeneity associated with firm scale.

The tests use an international panel of 13,373 firms representing 92 countries and 438 Trucost industries over 2005-2022. I collect panel data on stock returns $R_{i,t+1}$, the risk-free rate $R_{f,t}$, firm-level Scope 1 emissions $X_{i,t}$, firm value $V_{i,t}$, and standard firm characteristics $W_{i,t}$ (such as

market capitalization, market-to-book ratio, book leverage, profitability, investment, momentum, age, PPE, and volatility). The emissions data come from S&P Trucost while all other information is from Capital IQ. Following Pedersen (2025), I define emission intensity as $X_{i,t}/V_{i,t}$, where V is proxied by the book value of equity, and I define the percentage change in emissions as $\Delta X_{i,t} = (X_{i,t} - X_{i,t-1})/X_{i,t-1}$. To mitigate the influence of outliers I winsorize intensity and emissions growth at the 2.5% level. Table 2 reports summary statistics for the key empirical variables.

A direct test of scale invariance. A central implication of the knife-edge intensity-sufficiency conditions is a scale-invariance restriction: firms with the same intensity but different scale must have the same priced transition exposure. If this restriction holds, the premium per unit of intensity should not vary systematically with firm scale. To test it, each period I sort firms by size into five equal-count bins (baseline: book value of equity) and estimate the pooled regression

$$R_{i,t+1} - R_{f,t} = \alpha_t + \sum_{b=1}^{B} b_b \, D_{b,i,t}\Big(\frac{X_{i,t}}{V_{i,t}}\Big) + \gamma_t^\top W_{i,t} + \varepsilon_{i,t+1},$$

where $D_{b,i,t}$ indicates membership in size bin b. The specification includes $W_{i,t}$, industry×time fixed effects, and country fixed effects. Standard errors are double-clustered by industry and time. The null implied by Proposition 3 is $H_0 : b_1 = \cdots = b_B$, which I test using a Wald statistic based on the clustered covariance matrix.

Table 3 reports the results. Panel A shows that the estimated intensity premium varies materially across size bins. Panel B reports formal Wald tests of the cross-bin equality restrictions and shows that the rejection is not specific to a particular definition of scale. The same restrictions are rejected (or remain economically close to rejection) when bins are formed using market capitalization, sales, or assets instead of book equity. The key implication for Proposition 3 is the robust rejection of cross-bin equality, providing direct evidence against the knife-edge hypothesis that emission intensity summarizes priced transition exposure in a scale-invariant manner. This rejection indicates that the mapping from emissions into priced cash-flow exposure is not scale-invariant, consistent with exposure functions that depend separately on emission levels and firm scale.

Spanning tests: does intensity subsume levels? I complement the scale-invariance tests with asymmetric spanning tests that evaluate whether intensity spans levels, as required under intensity sufficiency, or whether the opposite spanning relation is more consistent with the data.

Guided by the incomplete-markets benchmark and the general factor framework, I estimate pooled regressions of excess returns on emission levels and emission intensity (along with controls),

$$R_{i,t+1} - R_{f,t} = \alpha_t + b_{X,t} X_{i,t} + \gamma_t^\top W_{i,t} + \varepsilon_{i,t+1}, \tag{6.1}$$

$$R_{i,t+1} - R_{f,t} = \alpha_t + b_{I,t} \frac{X_{i,t}}{V_{i,t}} + \gamma_t^\top W_{i,t} + \varepsilon_{i,t+1}, \tag{6.2}$$

and

$$R_{i,t+1} - R_{f,t} = \alpha_t + b_{X,t} X_{i,t} + b_{I,t} \frac{X_{i,t}}{V_{i,t}} + \gamma_t^\top W_{i,t} + \varepsilon_{i,t+1}. \tag{6.3}$$

Equations (6.1)–(6.3) are interpreted as *spanning restrictions*, not as a symmetric horse race. If emission intensity $X_{i,t}/V_{i,t}$ is sufficient in the sense of Definition 3.1, then it must span the return variation associated with the underlying exposure: conditional on $X_{i,t}/V_{i,t}$, emission levels $X_{i,t}$ should have no incremental explanatory power ($H_0 : b_{X,t} = 0$ in (6.3)). Conversely, if priced exposure contains a scale component, then levels can span intensity, so that conditional on $X_{i,t}$, the ratio $X_{i,t}/V_{i,t}$ adds little information ($H_0 : b_{I,t} = 0$). I report Wald tests of both restrictions based on the clustered covariance matrix.

Table 4 provides evidence consistent with the latter asymmetry. Emission levels are positively and statistically significantly related to both one-month- and twelve-month-ahead returns when entered on their own, and they remain positive and highly significant when intensity is included. By contrast, conditional on emission levels, the incremental coefficient on intensity is economically small and statistically indistinguishable from zero, and the explanatory power of the specification is essentially unchanged. In the language of spanning, these estimates suggest that levels span intensity in this reduced-form relation, whereas intensity does not span levels, which is inconsistent with intensity sufficiency.

These findings have a direct implication for the underlying exposure function. From the equilibrium pricing representation in Section 3,

$$\mathbb{E}_t[R_{i,t+1} - R_{f,t}] \approx \lambda_t \frac{g(Z_{i,t})}{V_{i,t}},$$

cross-sectional variation in expected returns reflects differences in value-normalized cash-flow exposure. If expected returns vary with emission levels conditional on intensity, then firms with identical $X_{i,t}/V_{i,t}$ but different scale must have different values of $g(Z_{i,t})/V_{i,t}$. This implies that dollar exposure $g(Z_{i,t})$ cannot be proportional to emissions alone and instead must scale non-proportionally

with firm value, so that value-normalized exposure depends on firm scale. Equivalently, the exposure function violates the homogeneity and scale-invariance conditions characterized in Proposition 3. The data are therefore consistent with mechanisms such as fixed compliance costs, scale-dependent pass-through, regulatory thresholds, or adjustment frictions, which generate exposure functions that depend separately on emission levels and firm scale.

The restrictions we test are not only statistically sharp but economically consequential. In the joint specification in Table 4, the coefficient of log(Scope 1) measures the return effect of emission scale holding intensity fixed. A one-standard-deviation increase in log(Scope 1) predicts a 0.35% increase in next-month expected returns (about 4.2% annualized). At the twelve-month horizon, the corresponding effect remains economically meaningful: a one-standard-deviation increase in emissions predicts a 0.11% increase in average monthly returns over the subsequent year (about 1.33% annualized). Thus, firms with similar $X_{i,t}/V_{i,t}$ but different emission scales earn systematically different expected returns, directly contradicting the scale-invariance and spanning restrictions implied by Proposition 3.

Within-size-bin spanning. A remaining concern is that the spanning asymmetry in Table 4 reflects slope heterogeneity associated with firm scale. If the price of transition exposure varies with size, then emission levels may appear to add explanatory power in pooled regressions even when intensity is the relevant exposure measure within scale classes. To address this concern directly, I re-estimate the joint levels-intensity specification (6.3) separately within size quintiles, using the same controls and fixed effects. By construction, firm scale is approximately fixed within each regression, so this design isolates whether emission levels add return-relevant information beyond intensity even among firms of comparable size.

Table 5 reports the results. Emission levels remain positively and significantly related to expected returns within every size bin, while the coefficient of intensity is economically small and statistically weak. This within-bin evidence strengthens the spanning conclusion in two ways. First, it rules out the interpretation that the pooled spanning results are driven primarily by residual size differences or generic size-related slope heterogeneity. Second, it directly targets the key implication of intensity sufficiency: if $X_{i,t}/V_{i,t}$ were a uniquely sufficient statistic for priced transition exposure, then conditioning on intensity should eliminate systematic return differences associated with emission scale even within narrow scale classes. The data reject this implication.

Concerns that the joint specification merely reflects mechanical ratio relationships are mitigated

by both the correlation structure of the data and the within-size-bin evidence. Emission intensity and log emissions are only moderately correlated, and intensity is close to orthogonal to firm size. Moreover, emission levels retain strong explanatory power even within narrow size bins, where firm scale is approximately fixed. These results indicate that the spanning rejection reflects genuine differences in priced exposure rather than mechanical denominator effects arising from the definition of intensity.

The asymmetric spanning result is also robust to alternative intensity definitions using assets and market capitalization. In contrast, scaling emissions by sales yields a sign reversal. Sales-based intensity enters with a negative coefficient, which becomes stronger and more significant once emission levels are included, even after controlling for ROE and industry fixed effects. This behavior indicates that sales-based intensity loads on a different priced dimension, reflecting pricing power or pass-through embedded in revenues, rather than serving as a sufficient statistic for exposure per unit of firm value.

Finally, the rejection of intensity sufficiency in this section does not rely on long-horizon predictability or on the magnitude of estimated premia. The objects being tested are cross-sectional restrictions implied by Proposition 3, scale invariance and spanning, which must hold at any horizon if emission intensity is a uniquely sufficient statistic for priced transition exposure. Horizon-dependent attenuation affects the interpretation of the time-varying price of risk, but it does not affect the validity of these sufficiency tests.

Changes in emissions. To connect more directly to the transition-risk channel in Section 5, I also consider a specification that allows both the level and the recent change in emissions to enter the exposure function. Specifically, I estimate

$$R_{i,t+1} - R_{f,t} = \alpha_t + b_{X,t} X_{i,t} + b_{\Delta X,t} \Delta X_{i,t} + \gamma_t^\top W_{i,t} + \varepsilon_{i,t+1}, \tag{6.4}$$

and report the results in Internet Appendix OA.E. Because $\Delta X_{i,t}$ is inherently more sensitive to timing and transitory noise than $X_{i,t}$, I view these estimates as supplementary. The appendix results indicate that emission changes can be associated with return predictability at short horizons, while the level effect is more stable across specifications and horizons.

Overall, the evidence rejects both knife-edge restrictions implied by intensity sufficiency. Scale-invariance tests (Table 3) reject homogeneity across firm size, while spanning tests (Tables 4-5) show that emission levels remain strongly priced conditional on intensity and within narrow size

classes. Intensity becomes redundant once levels are included, even among firms of similar scale. These findings therefore reject intensity sufficiency in the sense of Proposition 3. The results do not establish that emission levels are universally sufficient; rather, they demonstrate that the knife-edge conditions required for intensity sufficiency do not hold in the data, underscoring the need for a richer exposure-based characterization of climate risk premia. Developing and empirically disciplining such exposure functions is therefore a central task for future research.

7 Implications for Measurement, Allocation, and Policy

In this section, I develop implications of the exposure-based framework for measurement, capital allocation, and policy interpretation. The central insight is that asset prices reflect value-normalized exposure functions $g(Z_{i,t})/V_{i,t}$, while commonly used characteristics capture projections of this exposure onto selected metrics. When the chosen characteristic does not recover the underlying exposure function, this misalignment distorts both the measurement of climate risk and the allocation of capital. The subsections below illustrate this mechanism in a sequence of settings. Section 7.1 shows how firms' endogenous responses, such as efficiency improvements, can alter exposure in ways that are not captured by emission intensity, leading to capital misallocation. Section 7.2 demonstrates that aggregating heterogeneous characteristics into composite ESG measures mixes distinct exposure channels and obscures priced risk. Section 7.3 generalizes this insight by showing that when multiple economic mechanisms jointly determine exposure, no scalar characteristic can generically summarize priced risk. Finally, Section 7.4 revisits the policy benchmark to clarify why emission intensity arises naturally in implementation, even when it does not summarize equilibrium risk premia. Together, these results show that the choice of characteristic is not innocuous: it shapes both empirical inference and real economic outcomes.

7.1 Capital allocation and firm behavior

This section illustrates how misalignment between measured characteristics and underlying exposure functions can distort capital allocation and firm behavior. In particular, I show how endogenous energy efficiency can undermine emission intensity as a proxy for priced transition exposure. The goal is not to build a full production model, but to isolate a simple mechanism through which firms can improve commonly used greenness metrics while increasing their value-relevant exposure to priced climate or policy shocks.

The key insight is that firms respond to the characteristics that are measured and priced. When these characteristics do not coincide with the underlying exposure function $g(Z_{i,t})$, firms may optimally adjust behavior in ways that improve measured metrics but increase true exposure. A Jevons-type rebound provides a simple and economically relevant illustration of this mechanism. Improvements in energy efficiency lower marginal production costs, which induces firms to expand output. The expansion of production increases total energy use and emissions, potentially raising exposure to climate or policy shocks even as emissions per unit of output fall. As a result, firms that appear greener according to intensity measures can face higher equilibrium risk premia by increasing their effective exposure to priced shocks.

While the section is illustrative, the mechanism has direct implications for capital allocation. If investors rely on intensity-based measures that do not capture the relevant exposure function, capital may be directed toward firms that improve measured metrics without reducing, and potentially increasing, underlying transition risk.

Efficiency choice and rebound. At date t, firm i uses energy $E_{i,t}$ and chooses an efficiency parameter $a_{i,t} > 0$ to produce an energy service

$$S_{i,t} = a_{i,t}E_{i,t}, \qquad X_{i,t} = \gamma E_{i,t},\ \gamma > 0,$$

so that $a_{i,t}$ increases service per unit of energy (and per unit of emissions). Let P_t^E denote the real energy price and suppose operating profits admit the reduced form

$$\Pi_{i,t} = \pi_i(S_{i,t}) - P_t^E E_{i,t} - \Psi_i(a_{i,t}),$$

with π_i increasing and concave and Ψ_i the private cost of efficiency. For given $(P_t^E, a_{i,t})$, optimal energy demand $E_{i,t}^*(a_{i,t})$ satisfies

$$a_{i,t}\pi_i'(a_{i,t}E_{i,t}^*) = P_t^E.$$

A Jevons-type rebound region is characterized by

$$\frac{\partial E_{i,t}^*}{\partial a_{i,t}} \geq 0,$$

so that higher efficiency does not reduce, and may increase, energy use and therefore emissions $X_{i,t} = \gamma E_{i,t}^*(a_{i,t})$. Because emissions are induced by the equilibrium energy choice, any shock sensi-

tivity expressed in the primitives $(E^*_{i,t}, a_{i,t}, Z_{i,t})$ is equivalently a function of $(X_{i,t}, a_{i,t}, Z_{i,t})$, and its comparative statics with respect to efficiency need not be negative in the rebound region. Empirically, this implies that intensity can improve mechanically while priced exposure rises if efficiency shifts the firm into the rebound region, so intensity-based greenness need not be informative about the relevant exposure function $g(Z_{i,t})$.

Pricing with efficiency-dependent exposures. Let ζ_{t+1} denote an aggregate climate or policy shock and let $\varepsilon_{E,t+1}$ denote an energy-price (or energy-demand) shock. Write dividends as

$$D_{i,t+1} = \tilde{D}_{i,t+1} + g_\zeta(X_{i,t}, a_{i,t}, Z_{i,t})\,\zeta_{t+1} + g_E(X_{i,t}, a_{i,t}, Z_{i,t})\,\varepsilon_{E,t+1}, \tag{7.1}$$

where $Z_{i,t}$ collects other characteristics and $\tilde{D}_{i,t+1}$ is orthogonal (conditionally) to $(\zeta_{t+1}, \varepsilon_{E,t+1})$. The Jevons mechanism matters because efficiency affects energy demand and therefore both emissions and shock sensitivity, so the exposure coefficients in (7.1) generically depend on $(X_{i,t}, a_{i,t})$ jointly. More generally, efficiency can affect exposure not only through emissions but also through the economic incidence of climate shocks—for example through pass-through, adjustment costs, or regulatory thresholds—so that $g_\zeta(X_{i,t}, a_{i,t}, Z_{i,t})$ need not be proportional to emissions alone.

Under the same linear-factor pricing logic as in Proposition 4, expected excess returns load on value-normalized exposures:

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \lambda_t^{(\zeta)} \frac{g_\zeta(X_{i,t}, a_{i,t}, Z_{i,t})}{V_{i,t}} + \lambda_t^{(E)} \frac{g_E(X_{i,t}, a_{i,t}, Z_{i,t})}{V_{i,t}}, \tag{7.2}$$

with equilibrium prices of risk $(\lambda_t^{(\zeta)}, \lambda_t^{(E)})$ determined by preferences, risk sharing, and the aggregate exposure of cash flows and (where relevant) unspanned damages to $(\zeta_{t+1}, \varepsilon_{E,t+1})$. Equation (7.2) makes clear that the priced characteristics are the value-normalized exposure functions $g_\zeta(\cdot)/V_{i,t}$ and $g_E(\cdot)/V_{i,t}$, which depend on efficiency and emissions jointly. Once $a_{i,t}$ shifts energy use and hence shock sensitivity, there is no generic reason for premia to collapse to a function of $X_{i,t}/V_{i,t}$ alone.

A simple example with reversed comparative statics

To see how a rebound can raise premia, consider

$$\pi_i(S) = pS - \frac{c}{2}S^2, \qquad p > 0,\ c > 0,$$

and ignore $\Psi_i(a)$ for the moment. The optimal energy choice is

$$E^*_{i,t}(a_{i,t}) = \frac{a_{i,t}p - P^E_t}{ca^2_{i,t}} \quad \text{for } a_{i,t}p > P^E_t,$$

so that

$$\frac{\partial E^*_{i,t}}{\partial a_{i,t}} = \frac{2P^E_t - a_{i,t}p}{ca^3_{i,t}}.$$

Hence, for $a_{i,t} \leq 2P^E_t/p$, higher efficiency increases energy use and emissions.

Suppose the climate shock enters dividends through emission levels,

$$g_\zeta(X_{i,t}, a_{i,t}, Z_{i,t}) = \eta X_{i,t} = \eta\gamma E^*_{i,t}(a_{i,t}), \qquad g_E \equiv 0,$$

and the equilibrium price of climate risk satisfies $\lambda^{(\zeta)}_t > 0$. Then (7.2) reduces to

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \lambda^{(\zeta)}_t \frac{\eta\gamma E^*_{i,t}(a_{i,t})}{V_{i,t}}.$$

To isolate the exposure channel emphasized by the Jevons mechanism, consider the comparative static locally holding firm value $V_{i,t}$ fixed. This partial-equilibrium normalization captures how efficiency alters the firm's priced cash-flow exposure through equilibrium energy use and emissions, abstracting from the separate effect of efficiency on firm valuation through expected profits. In general equilibrium, changes in $a_{i,t}$ also affect $V_{i,t}$, but the exposure channel alone is sufficient to demonstrate that efficiency need not reduce priced climate exposure.

Under this normalization, in the rebound region,

$$\frac{\partial}{\partial a_{i,t}}\left(\mathbb{E}_t[R_{i,t+1}] - R_{f,t}\right)\Big|_{V_{i,t}} = \lambda^{(\zeta)}_t \frac{\eta\gamma}{V_{i,t}} \frac{\partial E^*_{i,t}}{\partial a_{i,t}} \geq 0,$$

with strict inequality for $a_{i,t} < 2P^E_t/p$. Thus, higher efficiency can increase equilibrium premia by raising emissions and hence value-normalized exposure to the priced climate factor. The full general-equilibrium comparative static additionally depends on how efficiency affects firm valuation through expected profits and continuation values, but the exposure channel alone is sufficient to demonstrate that efficiency improvements need not reduce priced climate exposure.

At the same time, higher efficiency increases service output per unit of energy and therefore reduces physical emissions intensity (emissions per unit of service), even as equilibrium emissions and priced exposure rise. As a result, physical or accounting intensity measures can improve while

the priced exposure determining expected returns increases, so intensity-based rankings need not align with equilibrium risk premia in rebound regions.

The Jevons mechanism illustrates how improvements in measured characteristics, such as emission intensity, can coincide with increases in value-relevant exposure to priced climate risk. When firms adjust efficiency in ways that affect energy use and emissions, the resulting exposure functions depend jointly on emissions and technological choices, so there is no general reason for priced characteristics to collapse to $X_{i,t}/V_{i,t}$ alone. This disconnect between measured metrics and underlying exposure is central to the misallocation channel discussed in this section.

7.2 ESG ratings and composite measures

The framework developed in this paper has direct implications for the interpretation of ESG ratings and other composite sustainability measures. In practice, widely used ESG scores aggregate a large number of firm characteristics—including emissions, energy efficiency, governance indicators, and disclosure metrics—into a single index. This aggregation is often motivated by the idea that combining multiple signals improves measurement of an underlying latent concept such as "sustainability" or "climate risk."

From the perspective of the exposure-based framework, however, such aggregation is theoretically justified only under restrictive conditions. Expected returns depend on value-normalized exposure functions $g_k(Z_{i,t})/V_{i,t}$ that map firm characteristics into sensitivities to climate and policy shocks. Different characteristics generally correspond to different underlying economic mechanisms and therefore to different exposure functions. For example, emission levels capture direct exposure to transition costs under carbon pricing, while energy efficiency, technology choices, or sector classifications reflect distinct channels through which firms are affected by climate shocks.

Aggregation across these characteristics implicitly assumes that they measure the same underlying exposure object, or at least that they are proportional to one another. When this assumption fails, composite measures do not recover the relevant exposure function but instead reflect projections of multiple, heterogeneous exposure channels onto a single index. As a result, variation in ESG scores may mix fundamentally different sources of risk and need not correspond to variation in priced climate exposure. The implications of this aggregation problem can be illustrated using a simple example.

Illustrative example: aggregation across mechanisms. The issue can be illustrated using three simple mechanisms that map emissions into cash-flow exposure.

Under a carbon tax, exposure is proportional to emission levels,

$$g(Z_{i,t}) = \eta X_{i,t}, \qquad \frac{g(Z_{i,t})}{V_{i,t}} \propto \frac{X_{i,t}}{V_{i,t}}.$$

Under a scale-dependent policy, exposure may be nonlinear in emissions,

$$g(Z_{i,t}) = X_{i,t}^2, \qquad \frac{g(Z_{i,t})}{V_{i,t}} \propto \frac{X_{i,t}^2}{V_{i,t}}.$$

Under a net-zero constraint, exposure may depend on deviations from a regulatory benchmark X^{NZ},

$$g(Z_{i,t}) = X_{i,t} - X^{NZ}, \qquad \frac{g(Z_{i,t})}{V_{i,t}} \propto \frac{X_{i,t} - X^{NZ}}{V_{i,t}}.$$

Each of these mechanisms implies a different priced characteristic. Now suppose a researcher or rating agency aggregates across these measures, for example by constructing

$$\tilde{X}_{i,t} = \frac{1}{3}\left(\frac{X_{i,t}}{V_{i,t}} + \frac{X_{i,t}^2}{V_{i,t}} + \frac{X_{i,t} - X^{NZ}}{V_{i,t}}\right).$$

This composite measure does not correspond to any underlying exposure function $g(Z_{i,t})$. Instead, it combines characteristics associated with distinct economic mechanisms into a single index. As a result, variation in $\tilde{X}_{i,t}$ need not map to variation in priced exposure, and regression coefficients based on such a measure lose their structural interpretation.

More generally, aggregation across characteristics associated with different mechanisms produces a projection of multi-dimensional exposure onto a single index. Unless the underlying exposure functions are proportional, this projection does not preserve the cross-sectional variation in priced exposure that determines equilibrium returns.

This issue is particularly relevant in practice, where ESG ratings are typically constructed as weighted averages of category-level scores. For example, rating agencies often combine environmental, social, and governance dimensions using predetermined weights, and environmental scores themselves may aggregate emissions intensity, absolute emissions, and other operational metrics. These procedures embed implicit assumptions about the relative importance and comparability of different characteristics, even though the underlying exposure functions may differ across firms and

across economic mechanisms.

Within the framework of this paper, such aggregation can distort both measurement and interpretation. If investors rely on composite scores that do not align with the relevant exposure functions, asset prices will reflect projections of exposure onto the chosen metric rather than the underlying exposure itself. This can lead to capital allocation that favors firms scoring highly on aggregated measures while leaving the value-relevant exposure to climate risk unchanged or even increased.

More generally, the framework suggests that the choice of characteristics is not merely a statistical issue but a structural one. Identifying the appropriate measure of climate risk requires understanding the economic mechanism that maps firm characteristics into cash-flow exposure. Aggregation across characteristics associated with different mechanisms obscures this mapping and can therefore lead to misleading inferences about both risk premia and firm-level exposure. These considerations become particularly relevant when multiple economic mechanisms jointly determine firms' exposure to climate risk, as is likely to be the case in practice.

7.3 When do multiple exposure channels coexist?

The analysis above highlights that different economic mechanisms map firm characteristics into distinct exposure functions. In practice, these mechanisms are likely to operate jointly. In such environments, expected returns take the form

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \sum_k \lambda_{k,t} \frac{g_k(Z_{i,t})}{V_{i,t}},$$

where each $g_k(\cdot)$ corresponds to a separate channel through which climate or policy shocks affect cash flows.

When multiple exposure channels are present, there is no reason for the value-normalized exposure vector $\{g_k(Z_{i,t})/V_{i,t}\}_k$ to collapse to a scalar function of any single firm characteristic. Any univariate measure, including emission intensity or composite ESG scores, therefore recovers at best a projection of the underlying multidimensional exposure. As a result, sufficiency requires strong restrictions on the joint structure of exposure functions, and is unlikely to hold generically.

Heterogeneity in investor preferences further amplifies this effect. As shown in Section 3.3, different investors place different weights on transition risk and hedging demand arising from non-tradable climate damages. In a multi-channel environment, this implies that the equilibrium price

of risk reflects a weighted aggregation of heterogeneous valuations across distinct exposure channels. Consequently, both the mapping from firm characteristics into priced exposure and the pricing of that exposure depend on the interaction between multiple mechanisms and heterogeneous investor preferences.

These considerations reinforce the central implication of the paper: identifying priced climate risk requires recovering the underlying exposure functions rather than relying on scalar proxies that aggregate across heterogeneous channels.

7.4 Planner, social cost of carbon, and a Pigouvian tax

This subsection provides a policy benchmark that clarizes when emission intensity can serve as a valid summary of climate exposure. In the complete-markets environment underlying sustainable-discount-rate approaches, the relevant object is a deterministic implementation wedge: policy-induced distortions to firms' cash flows scale linearly with emissions and are expressed on a per-unit-of-value basis. As a result, value-normalized exposure collapses to emission intensity. In this setting, intensity is not a projection but the correct underlying object, and therefore emerges naturally as a sufficient statistic for implementing policy objectives. This benchmark highlights that the role of emission intensity depends on the structure of the exposure function. In the equilibrium asset-pricing environment studied in the main analysis, exposure functions $g(Z_{i,t})$ are determined by technology, policy design, and firm behavior and need not be proportional to emissions. As a result, intensity typically reflects a projection of multidimensional exposure rather than the exposure itself. The planner benchmark therefore clarifies why intensity-based measures are prevalent in policy design, while also making clear that their validity hinges on restrictive conditions that need not hold in equilibrium pricing.

Formally, consider again dates $t = 0, 1$ and a single consumption good. A representative agent has utility

$$U = u(C_0) + \beta\Big(u(C_1) - d(X_1)\Big), \tag{7.3}$$

where C_0 and C_1 denote aggregate consumption at dates 0 and 1, $\beta \in (0, 1)$ is the subjective discount factor, and $d : \mathbb{R}_+ \to \mathbb{R}_+$ is a strictly increasing, convex damage function of aggregate emissions $X_1 \geq 0$. The function $d(\cdot)$ can be interpreted as the expected disutility from climate damages, for example $d(X_1) = \mathbb{E}[\Gamma(\zeta) \mid X_1]$ in a reduced-form sense. The per-period utility u is strictly increasing and concave.

Firm i produces a deterministic date-1 payoff $Y_i \geq 0$ per unit of scale and emits $X_i \geq 0$ per unit of scale. If I_i denotes the scale of firm i at date 0, we can aggregate emissions as

$$X_1 = \sum_{i=1}^{N} X_i I_i. \tag{7.4}$$

Let G_0 denote the date-0 endowment of the consumption good. The resource constraints are

$$C_0 + \sum_{i=1}^{N} I_i \leq G_0, \qquad C_1 = \sum_{i=1}^{N} Y_i I_i. \tag{7.5}$$

The technological mapping from I_i to (Y_i, X_i) is kept implicit. (Y_i, X_i) are treated as primitive characteristics of one unit of firm i, and the planner chooses the scale I_i.

The social planner chooses $(C_0, C_1, \{I_i\}_{i=1}^N)$ to maximize (7.3) subject to (7.4)-(7.5). Let λ_0 and λ_1 denote the Lagrange multipliers on the two resource constraints. The planner's Lagrangian is

$$\mathcal{L} = u(C_0) + \beta\big(u(C_1) - d(X_1)\big) + \lambda_0\Big(G_0 - C_0 - \sum_i I_i\Big) + \lambda_1\Big(\sum_i Y_i I_i - C_1\Big).$$

The first-order conditions for C_0 and C_1 are

$$u'(C_0) = \lambda_0, \qquad \beta u'(C_1) = \lambda_1. \tag{7.6}$$

The first-order condition for I_i is

$$-\lambda_0 + \lambda_1 Y_i - \beta d'(X_1) X_i = 0. \tag{7.7}$$

Combining (7.6) and (7.7) yields

$$\frac{\lambda_0}{\lambda_1} = Y_i - \frac{\beta d'(X_1)}{\lambda_1} X_i = Y_i - \frac{d'(X_1)}{u'(C_1)} X_i. \tag{7.8}$$

The shadow cost of an additional unit of emissions in terms of the consumption numeraire is defined as the social cost of carbon,

$$S \equiv \frac{d'(X_1)}{u'(C_1)}. \tag{7.9}$$

Expression (7.8) can then be written as

$$\frac{\lambda_0}{\lambda_1} = Y_i - SX_i. \tag{7.10}$$

Equation (7.10) shows that, at the planner optimum, a marginal increase in scale I_i raises date-1 resources by Y_i but also increases the planner's marginal damage by SX_i. It is therefore convenient to interpret $Y_i - SX_i$ as the planner-implied net date-1 payoff (in consumption units) generated by one unit of firm i's scale.

To express this condition in present-value form, define the planner-implied intertemporal discount factor as

$$q \equiv \frac{\lambda_1}{\lambda_0} = \beta \frac{u'(C_1)}{u'(C_0)}. \tag{7.11}$$

Then (7.10) is equivalent to

$$1 = q(Y_i - SX_i). \tag{7.12}$$

Thus, the date-0 shadow value of one unit of scale is $q(Y_i - SX_i)$, the present value of its net date-1 payoff.

For later comparison, it is convenient to parameterize the planner-implied discount factor by a (gross) risk-free rate r via

$$q \equiv \frac{\lambda_1}{\lambda_0} = \frac{1}{1+r}. \tag{7.13}$$

A Pigouvian carbon tax τ per unit of emissions, levied uniformly on firms and rebated lump-sum to the representative household, decentralizes the planner's allocation if $\tau = S$. Under such a tax, firm i's date-1 net payoff per unit of scale is $Y_i - \tau X_i$, and its date-0 value is

$$V_i = q(Y_i - \tau X_i) = \frac{Y_i - \tau X_i}{1+r}. \tag{7.14}$$

If $\tau = S$, then (7.12) and (7.14) coincide, implying that the competitive equilibrium with tax $\tau = S$ reproduces the first-best allocation.

7.4.1 Sustainable discount rates and the emission-intensity wedge

The sustainable-discount-rate approach asks whether the same allocation that would be achieved by a Pigouvian carbon tax can instead be implemented by adjusting firms' discount rates while leaving their cash flows untaxed. In the one-period environment above, this equivalence can be

made explicit and directly related to emission intensity.

Fix a firm i and suppose that, under the carbon tax τ, its date-0 value is V_i given by (7.14). Let r denote the financial discount rate that applies in the absence of any climate-related discount-rate adjustment. A sustainable discount rate r_i^x for firm i is defined implicitly by the condition that the present value of the taxed cash flow discounted at r equals the present value of the untaxed cash flow discounted at r_i^x, that is,

$$\frac{Y_i - \tau X_i}{1+r} = \frac{Y_i}{1+r_i^x}. \tag{7.15}$$

Solving (7.15) for r_i^x gives

$$1 + r_i^x = \frac{Y_i}{Y_i - \tau X_i}(1+r). \tag{7.16}$$

Equation (7.16) expresses the sustainable discount rate as a nonlinear function of the financial rate r, the tax τ, and the ratio $\tau X_i/Y_i$.

For small wedges and moderate discount rates, a first-order approximation in $\tau X_i/Y_i$ is informative. Writing $\varepsilon_i \equiv \tau X_i/Y_i$ and expanding the right-hand side of (7.16) to first order in ε_i yields

$$1 + r_i^x \approx (1+r)(1+\varepsilon_i),$$

so that

$$r_i^x - r \approx \varepsilon_i = \tau \frac{X_i}{Y_i}. \tag{7.17}$$

Let V_i denote the firm's value under the tax as in (7.14). For small τ, we have $V_i \approx Y_i/(1+r)$, and hence

$$\frac{X_i}{Y_i} \approx \frac{X_i}{(1+r)V_i} \approx \frac{X_i}{V_i},$$

where the last approximation absorbs the factor $1+r$ into the first-order approximation (and is numerically innocuous at annual rates). Substituting into (7.17) yields the familiar emission-intensity wedge,

$$r_i^x \approx r + \tau \frac{X_i}{V_i}. \tag{7.18}$$

If the tax τ coincides with the SCC S in (7.9), then (7.18) links the sustainable discount rate directly to the SCC and emission intensity:

$$r_i^x \approx r + S \frac{X_i}{V_i}. \tag{7.19}$$

More generally, suppose that the prevailing carbon tax is τ while the planner's SCC is S. The additional wedge required to move from the current tax to the first-best tax is $S - \tau$. Consider a small change $\mathrm{d}\tau$ in the tax and equate the induced change in firm value to that from a small change $\mathrm{d}r_i$ in the discount rate:

$$\mathrm{d}V_i^{(\tau)} = -\frac{X_i}{1+r}\mathrm{d}\tau, \qquad \mathrm{d}V_i^{(r)} = -\frac{V_i}{1+r}\mathrm{d}r_i.$$

Setting $\mathrm{d}V_i^{(\tau)} = \mathrm{d}V_i^{(r)}$ implies

$$\mathrm{d}r_i = \frac{X_i}{V_i}\mathrm{d}\tau.$$

Applying this with $\mathrm{d}\tau = S - \tau$ and linearizing around the initial allocation yields

$$r_i^x \approx r + (S - \tau)\frac{X_i}{V_i}. \tag{7.20}$$

Equations (7.9) and (7.20) formalize the sustainable-discount-rate representation developed by Pedersen (2025). The SCC S is the planner's shadow value of emissions in units of the consumption numeraire, and, to a first-order approximation, the same allocation that would be achieved by adjusting the carbon tax from τ to S can be implemented by tilting each firm's discount rate in proportion to its emission intensity X_i/V_i. In this complete-markets benchmark, X_i/V_i is the sufficient statistic for how strongly a firm's cost of capital must be adjusted to implement the planner's allocation.

This is fundamentally an implementation result rather than a restriction on equilibrium pricing. Equation (7.20) characterizes the deterministic discount-rate wedge required to decentralize a first-best allocation under complete markets. The appearance of emission intensity reflects the normalization of this wedge per unit of firm value, not a statement about how risk is priced. In contrast, equilibrium asset pricing depends on how climate and policy shocks enter firms' cash flows through exposure functions $g(Z_{i,t})$. Once one allows for heterogeneous investors and incomplete risk sharing, the characteristics that govern equilibrium risk premia need not collapse to X_i/V_i and can instead depend on emission levels and more general functions of firm characteristics. The planner benchmark therefore clarifies why emission intensity emerges naturally in policy implementation, while highlighting that equilibrium risk premia depend on underlying exposure functions rather than on intensity alone.

8 Conclusion

In this paper, I develop an equilibrium model of climate risk premia. Climate risk premia are determined by two objects: the equilibrium price of risk, λ, and the economic mechanism that maps firm characteristics into cash-flow exposure, $g(Z_{i,t})$. The price of risk reflects aggregate conditions, such as policy uncertainty, risk aversion, total market emissions, and investor composition, while the exposure function is shaped by firm technology, policy design, and firm behavior. Under incomplete markets, the price of risk can be decomposed into components reflecting compensation for climate risk and hedging demand, but does not determine which firm characteristics govern exposure. In turn, the form of the exposure function is independent of market completeness.

This separation between the price of risk and the exposure function implies that identifying climate risk premia requires specifying the relevant exposure function. I characterize the conditions under which a given characteristic summarizes climate risk premia using emission intensity as an example. Emission intensity is sufficient only when the exposure function satisfies homogeneity and scale-invariance conditions. These conditions arise mechanically in planner implementations, where wedges are proportional to emissions per unit of firm value, and reflect restrictions on the exposure function rather than features of market completeness, but do not generally hold in equilibrium asset pricing. More generally, commonly used carbon metrics need not coincide with the value-normalized exposure $g(Z_{i,t})/V_{i,t}$ implied by the underlying mechanism. In this sense, the choice of characteristic is not a measurement decision but a statement about the underlying economic mechanism.

This distinction clarifies how to select empirically relevant characteristics. A valid characteristic must correspond to the value-normalized exposure $g(Z_{i,t})/V_{i,t}$ implied by the underlying mechanism. Absent this mapping, regression coefficients reflect projections of equilibrium risk premia onto the chosen metric rather than structural parameters. Empirical tests reject the sufficiency restrictions, suggesting that commonly used metrics do not fully capture the relevant exposure functions and that part of the variation in estimates across the literature may reflect differences in the underlying economic objects being measured.

An important implication of my framework is that misidentifying the relevant exposure function leads to distorted pricing, capital allocation, and firm incentives. When investors or regulators rely on characteristics that do not correspond to the underlying exposure $g(Z_{i,t})/V_{i,t}$, equilibrium prices reflect projections onto the chosen metric rather than true risk. This mispricing directs capital

toward firms that appear low-risk under the selected characteristic, even if their underlying exposure remains high, and induces firms to optimize the measured metric rather than the underlying exposure. As a result, decarbonization efforts may improve reported indicators without reducing transition risk. This logic extends directly to sustainable finance practice: regulatory taxonomies and disclosure standards often emphasize particular metrics, implicitly assuming the conditions under which those measures are sufficient for pricing. When these conditions do not hold, portfolios that satisfy regulatory or disclosure-based criteria can nonetheless carry substantial climate transition risk if the underlying exposure depends on dimensions the metric does not capture.

Beyond metric choice, the framework provides a micro-foundation for the green and brown classifications central to the climate-finance literature (e.g., Pastor et al. (2021)). Rather than treating these types as exogenous labels, the analysis endogenizes them as equilibrium exposure functions shaped by technology and fundamentals. A firm's climate-risk profile is therefore a dynamic object: changes in efficiency, production structure, or policy exposure can alter priced risk even when conventional ESG metrics improve.

The framework provides a disciplined approach to empirical work. Emission-level specifications are not arbitrary alternatives to intensity. They arise from specific exposure functions implied by the underlying mechanism. More generally, testing scale-invariance and spanning restrictions offers a template for evaluating whether a proposed climate-risk metric is theoretically coherent. Future research should structurally estimate the exposure functions $g_k(Z_{i,t})$ implied by specific policy and technology channels, quantify the relative importance of transition risk and preference-driven greenium components, and extend the framework to incorporate dynamic investment and abatement decisions.

Tables

Table 1: Using the model: priced objects under alternative exposure mechanisms

Economic mechanism	**Exposure structure** $g(Z_{i,t})$	**Object priced in equilibrium**	**Regression object**
Per-unit transition risk (taxes, permits, linear policy shocks)	$g(Z_{i,t}) = \eta X_{i,t}$	Emission scale, conditional on firm value	$X_{i,t}$
Planner implementation (complete markets, SCC-based policy)	Deterministic loss $S_t X_{i,t}$	Firm-specific discount-rate wedge	$X_{i,t}/V_{i,t}$
Scale-invariant equilibrium (homogeneous exposure benchmark)	$g(Z_{i,t}) = \kappa_t X_{i,t}$	Priced exposure identical for firms with equal intensity	$X_{i,t}/V_{i,t}$
Trajectory-based regulation (policy responds to changes or trends)	$g(Z_{i,t}) = \phi_1 X_{i,t} + \phi_2 \Delta X_{i,t}$	Emission levels and changes	$(X_{i,t},\, \Delta X_{i,t})$
Path-based constraints / net-zero (benchmarks, phase-out schedules)	$g(Z_{i,t}) = \vartheta_1 X_{i,t} + \vartheta_2 (X_{i,t} - X_{i,t}^{NZ})$	Emissions and distance to targets	$(X_{i,t},\, X_{i,t} - X_{i,t}^{NZ})$

Table 2: **Summary statistics**

The sample includes listed companies from 92 countries over 2005-2022. *Returns* are monthly stock returns (in percent). Scope 1 emission levels (X) are in metric tons of CO_2 equivalent. Book value of equity (V) is in millions of US dollars. Emission intensity (X/V) is the ratio of emissions to book value of equity. Scope 1 growth rate is the year-over-year percentage change in emissions. Statistics reported are mean, median, and standard deviation across all observations.

Variable / Statistic	Mean	Median	St. dev.
Returns (in %)	0.890	0.348	12.134
Scope 1 levels (X)	1,696,164	26,141	11,700,000
Book value of equity (V)	333,602	4,967	12,900,000
Intensity (X/V)	1.233	0.048	3.619
Log(Scope 1)	10.356	10.174	2.850
Scope 1 growth rate	0.086	0.023	0.432
Number of firms: 13,373			
Number of countries: 92			
Number of industries: 438			

Table 3: **Predicting Stock Returns with Emission Intensity and Tests of Scale Invariance**

The sample is at the firm-month level and includes listed companies from 92 countries over 2005-2022. The dependent variable is monthly stock returns ($Returns_{i,t+1}$). Each period, firms are sorted by book value of equity into quintiles ($Size\ bin$). Emission intensity (X/V) is the ratio of Scope 1 emissions to book value. All regressions include industry × time fixed effects and country fixed effects. Standard errors (in parentheses) are double-clustered by industry and time. ***, **, and * denote statistical significance at the 1%, 5%, and 10% levels, respectively. Panel B reports F-statistics and p-values from Wald tests of the null hypothesis that coefficients on intensity are equal across all five size bins, based on the specification in Panel A, column (2). The baseline uses book value of equity for scaling; alternative specifications use market capitalization, sales, or total assets.

Appendix

A.1 Proofs and derivations

Proof of Proposition 1. By (3.3), for any h that holds a positive amount of stock i we have

$$\frac{\mu_i - V_i R_f}{\eta X_i} = \alpha_h \sigma_\zeta^2 \delta_h.$$

Since this ratio must be equalized across all stocks i and all households h with interior holdings, it must equal a common scalar λ:

$$\frac{\mu_i - V_i R_f}{\eta X_i} = \lambda \quad \forall i,$$

which yields (3.4). Substituting back gives $\alpha_h \sigma_\zeta^2 \delta_h = \lambda$, which yields (3.5). □

Proof of Proposition 2. In the static CARA-normal environment, aggregate consumption net of damages is $C_{h,1} - \phi_h \Gamma_1 = C_{h,1} - \phi_h \kappa \bar{X}\, \zeta_1$, so each household's SDF is exponential-affine in the climate shock,

$$m_{h,1} = \beta \frac{u_c^h(C_{h,1} - \phi_h \Gamma_1)}{u_c^h(C_{h,0} - \phi_h \Gamma_0)} \propto \exp\big(\alpha_h \phi_h \kappa \bar{X}\, \zeta_1\big),$$

where the proportionality absorbs β and all terms measurable at date 0. With mean-variance/CARA aggregation, the equilibrium (aggregate) SDF that prices all traded assets is the risk-tolerance-weighted average of individual SDF loadings, hence

$$m_1 \propto \exp\big(B\, \zeta_1\big), \qquad B = \kappa \bar{X} \frac{\sum_{h=1}^H \frac{\phi_h}{\alpha_h}}{\sum_{h=1}^H \frac{1}{\alpha_h}}.$$

Firm i's payoff (dividend) loads on the same shock with exposure ηX_i in the baseline specification, so $D_i = \tilde{D}_i + \eta X_i \zeta_1$ with $\tilde{D}_i \perp \zeta_1$. Using the Euler equation $1 = \mathbb{E}[m_1 R_i]$ and a second-order (mean-variance) expansion yields the standard linear pricing relation

$$\mathbb{E}[R_i] - R_f = -\operatorname{Cov}(R_i, \log m_1) = \sigma_\zeta^2 \,(\eta X_i)\,\Big(1 - B\Big),$$

where we used $\log m_1 = \text{const} + B\zeta_1$ and $\operatorname{Cov}(\zeta_1, \zeta_1) = \sigma_\zeta^2$. Aggregating across firms gives the climate factor price

$$\lambda = \frac{\sigma_\zeta^2 \bar{X}}{\sum_{h=1}^H \frac{1}{\alpha_h}} \Big(\eta - \kappa \sum_{h=1}^H \phi_h\Big),$$

which is (3.8). □

Proof of Proposition 3. Condition (iii) implies that, for any fixed intensity level $u \in \mathbb{R}_+$, all firms with $X_{i,t}/V_{i,t} = u$ share the same exposure $g(Z_{i,t})/V_{i,t}$. Define $\varphi_t(u)$ to be this common value:

$$\varphi_t(u) \equiv \frac{g(Z_{i,t})}{V_{i,t}} \quad \text{for any firm } i \text{ with } \frac{X_{i,t}}{V_{i,t}} = u.$$

Condition (i) ensures that intensities span an open subset of $\mathbb{R}_+$, so that φ_t can be defined on an interval rather than on a finite set. This establishes (3.15).

To obtain (3.16), fix a firm with characteristics $(X_{i,t}, V_{i,t})$ and intensity $u = X_{i,t}/V_{i,t}$. By homogeneity of degree one in $(X_{i,t}, V_{i,t})$, for any $\lambda > 0$,

$$g(Z_{i,t}; \lambda X_{i,t}, \lambda V_{i,t}) = \lambda\, g(Z_{i,t}; X_{i,t}, V_{i,t}).$$

Dividing both sides by $\lambda V_{i,t}$ yields

$$\frac{g(Z_{i,t}; \lambda X_{i,t}, \lambda V_{i,t})}{\lambda V_{i,t}} = \frac{g(Z_{i,t}; X_{i,t}, V_{i,t})}{V_{i,t}}.$$

The left-hand side is the value-normalized exposure of a firm whose intensity remains u (since $(\lambda X_{i,t})/(\lambda V_{i,t}) = u$). By condition (iii), it depends only on u and therefore equals $\varphi_t(u)$, while the right-hand side equals $\varphi_t(u)$ by definition. Hence

$$\frac{g(Z_{i,t})}{V_{i,t}} = \varphi_t\left(\frac{X_{i,t}}{V_{i,t}}\right),$$

which restates (3.15).

Under the additional assumption in the proposition that the mapping is linear in size (equivalently, that $g(Z_{i,t})/V_{i,t}$ is proportional to $X_{i,t}/V_{i,t}$ on the relevant support), there exists a scalar κ_t such that for all firms,

$$\frac{g(Z_{i,t})}{V_{i,t}} = \kappa_t \frac{X_{i,t}}{V_{i,t}}.$$

Multiplying both sides by $V_{i,t}$ yields $g(Z_{i,t}) = \kappa_t X_{i,t}$ and establishes (3.16). Uniqueness in the sense of Definition 3.1 follows because any one-factor representation observationally equivalent to (3.14) must use a characteristic proportional to the priced characteristic $g(Z_{i,t})/V_{i,t}$, hence proportional to $X_{i,t}/V_{i,t}$ under (3.16). □

A Internet Appendix: Robustness to nonlinear damages and multiple climate shocks

This section shows that the main asset-pricing implications of our framework are robust to nonlinear damage functions and to the presence of multiple climate shocks (for example, physical, policy, and technology shocks). In particular, I show that under standard small-shock approximations the pricing kernel remains affine in the climate factors, expected excess returns remain linear in firm-specific exposure coefficients, and the relevant priced characteristics are generic functions $g_k(Z_{i,t})$ of firm characteristics rather than a uniquely determined emission-intensity statistic $X_{i,t}/V_{i,t}$.

A.1 Nonlinear damages in a single climate factor

I first extend the static damage specification to allow for nonlinear dependence on the climate shock. For expositional clarity, I work in a one-period environment. The dynamic case follows by applying the same local arguments period by period.

Let ζ be a scalar climate factor with $\mathbb{E}[\zeta] = 0$ and $\mathrm{Var}(\zeta) = \sigma_\zeta^2 \in (0, \infty)$, and let aggregate emissions be $\bar{X} = \sum_i X_i$ as before. Instead of the linear damage function $\Gamma = \kappa \bar{X} \zeta$, suppose that damages are given by

$$\Gamma = h(\bar{X}, \zeta), \tag{A.1}$$

where $h : \mathbb{R}_+ \times \mathbb{R} \to \mathbb{R}$ is twice continuously differentiable and satisfies $h(\bar{X}, 0) = 0$. A quadratic specification, for example,

$$h(\bar{X}, \zeta) = \kappa_1 \bar{X} \zeta + \frac{1}{2} \kappa_2 \bar{X} \zeta^2, \tag{A.2}$$

is included as a special case.

Household h has CARA preferences over climate-adjusted consumption,

$$U^h = \mathbb{E}\Big[u^h\big(C_1^h - \phi_h \Gamma\big)\Big], \qquad u^h(y) = -\exp(-\alpha_h y),$$

with $\alpha_h > 0$ and $\phi_h \geq 0$. Writing

$$Y_h \equiv C_1^h - \phi_h h(\bar{X}, \zeta),$$

and using a second–order Taylor expansion of h around $(\bar{X}, 0)$, we obtain

$$h(\bar{X}, \zeta) = h_\zeta(\bar{X}, 0)\zeta + \frac{1}{2} h_{\zeta\zeta}(\bar{X}, 0)\zeta^2 + o(\zeta^2), \tag{A.3}$$

where h_ζ and $h_{\zeta\zeta}$ denote the first and second partial derivatives with respect to ζ. Substituting (A.3) into Y_h yields

$$Y_h = \tilde{C}_1^h - \phi_h h_\zeta(\bar{X}, 0)\zeta - \frac{1}{2}\phi_h h_{\zeta\zeta}(\bar{X}, 0)\zeta^2 + o(\zeta^2),$$

where $\tilde{C}_1^h$ collects terms independent of ζ. To isolate the stochastic components, define the centered square

$$\tilde{\zeta}^2 \equiv \zeta^2 - \mathbb{E}[\zeta^2],$$

and rewrite Y_h as

$$Y_h = \bar{Y}_h + \beta_h^{(1)}\zeta + \beta_h^{(2)}\tilde{\zeta}^2 + o(\zeta^2), \tag{A.4}$$

for suitable constants $\bar{Y}_h, \beta_h^{(1)}, \beta_h^{(2)}$ that depend on $(\alpha_h, \phi_h, \bar{X})$ and on the moments of ζ. Under the assumption that ζ is conditionally normal and that higher-order terms are negligible, the pair $(\zeta, \tilde{\zeta}^2)$ can be treated as a two-dimensional factor vector with mean zero and finite second moments.

The CARA-normal structure implies that each household's portfolio problem again admits a mean-variance representation in terms of Y_h, now with respect to the joint distribution of $(\zeta, \tilde{\zeta}^2)$. Aggregating across households and solving for asset prices leads to an affine SDF of the form

$$m = \exp\big(-A - B^{(1)}\zeta - B^{(2)}\tilde{\zeta}^2\big), \tag{A.5}$$

with factor loadings $B^{(1)}$ and $B^{(2)}$ determined by the distribution of (α_h, ϕ_h) and by the coefficients $h_\zeta(\bar{X}, 0)$ and $h_{\zeta\zeta}(\bar{X}, 0)$.

Suppose now that firm i's dividend takes the reduced-form specification

$$D_i = \mu_i + g_1(Z_i)\zeta + g_2(Z_i)\tilde{\zeta}^2, \tag{A.6}$$

where Z_i collects firm characteristics and g_1, g_2 are measurable functions. A log-linear approximation to the Euler equation $\mathbb{E}[mR_i] = 1$ then yields

$$\mathbb{E}[R_i] - R_f \approx \lambda^{(1)} g_1(Z_i) + \lambda^{(2)} g_2(Z_i), \tag{A.7}$$

for factor prices of climate risk $\lambda^{(1)}, \lambda^{(2)}$ that are linear functions of $(B^{(1)}, B^{(2)})$ and of the conditional second moments of $(\zeta, \tilde{\zeta}^2)$. Expression (A.7) shows that allowing for quadratic (or more

general smooth) damages in ζ does not alter the linear factor structure: it simply enlarges the set of priced characteristics from a single function $g(Z_i)$ to a vector $(g_1(Z_i), g_2(Z_i))$, corresponding to exposure to the linear and quadratic components of the climate factor. In particular, if the technological channel through which ζ enters cash flows remains proportional to emission levels, as in

$$g_1(Z_i) = \eta_1 X_i, \qquad g_2(Z_i) = \eta_2 X_i,$$

then (A.7) implies that expected excess returns are proportional to X_i with a combined price of risk $\lambda^{(1)}\eta_1 + \lambda^{(2)}\eta_2$, and the qualitative conclusion that emission levels act as the relevant exposure remains unchanged. More generally, the quadratic damage term induces an additional priced characteristic $g_2(Z_i)$ whose functional form is determined by the way ζ^2 enters the technology and damage processes, but there is no mechanism that generically restores emission intensity X_i/V_i as a unique sufficient statistic.

A.2 Multiple climate shocks: physical, policy, and technology factors

I next allow for multiple climate-related shocks. Let $f_{t+1} = (f_{1,t+1}, \ldots, f_{K,t+1})^\top$ be a vector of K mean-zero factors that may represent, for example, a physical damage factor, a policy or carbon-price factor, and a technology factor. As in Section 4, suppose that firm i's dividend can be written as

$$D_{i,t+1} = \mu_{i,t+1} + \sum_{k=1}^{K} g_k(Z_{i,t}) f_{k,t+1}, \tag{A.8}$$

where $Z_{i,t}$ includes $(X_{i,t}, V_{i,t})$ and any other relevant characteristics, and $g_k(\cdot)$ are exposure functions determined by technology, market structure, and the incidence of policy. Climate damages are now given by a general function

$$\Gamma_t = H(\bar{X}_{t-1}, f_t), \tag{A.9}$$

where H is twice continuously differentiable in its arguments. Under CARA preferences $u^h(y) = -\exp(-\alpha_h y)$, household h's climate-adjusted consumption takes the form

$$Y_{h,t+1} = \tilde{C}_{h,t+1} - \phi_h H(\bar{X}_t, f_{t+1}).$$

A second-order Taylor expansion of H around a baseline $(\bar{X}_t, f_{t+1}) = (\bar{X}_t, 0)$ yields

$$H(\bar{X}_t, f_{t+1}) = H(\bar{X}_t, 0) + \sum_{k=1}^{K} H_k(\bar{X}_t, 0) f_{k,t+1} + \frac{1}{2} \sum_{k,\ell=1}^{K} H_{k\ell}(\bar{X}_t, 0) f_{k,t+1} f_{\ell,t+1} + o(\|f_{t+1}\|^2), \quad \text{(A.10)}$$

where H_k and $H_{k\ell}$ denote the first and second partial derivatives of H with respect to its factor arguments.

Under the maintained small-shock assumption, the leading-order contribution of the quadratic terms in (A.10) to the mean-variance approximation can be summarized by a finite set of additional factors constructed from products $f_{k,t+1} f_{\ell,t+1}$, for example their centered versions $f_{k,t+1} f_{\ell,t+1} - \mathbb{E}_t[f_{k,t+1} f_{\ell,t+1}]$. Aggregating across households and solving the mean-variance portfolio problem then yields an affine SDF of the form

$$m_{t+1} = \exp\Big(- A_t - \sum_{k=1}^{K} B_{k,t} f_{k,t+1} - \sum_{k,\ell=1}^{K} C_{k\ell,t}\, \tilde{f}_{k\ell,t+1} \Big), \quad \text{(A.11)}$$

where $\tilde{f}_{k\ell,t+1}$ are centered quadratic factor terms and the coefficients $B_{k,t}, C_{k\ell,t}$ are functions of (α_h, ϕ_h) and of the derivatives $H_k(\bar{X}_t, 0)$ and $H_{k\ell}(\bar{X}_t, 0)$. Although dividends in (A.8) are linear in the primitive factors $f_{k,t+1}$, the stochastic discount factor in (A.11) depends on both the linear factors and their centered quadratic combinations $\tilde{f}_{k\ell,t+1}$. As a result, the covariance $\mathrm{Cov}_t(m_{t+1}, D_{i,t+1})$ that determines expected returns involves cross-moments between $f_{k,t+1}$ and $\tilde{f}_{k\ell,t+1}$. These interactions generate induced exposure coefficients associated with the quadratic factor terms even though the primitive dividend process is linear. The resulting functions $\tilde{g}_{k\ell}(Z_{i,t})$ therefore represent effective cash-flow exposures arising from the joint dependence of the SDF and dividends on the underlying climate factors, rather than primitive quadratic loadings in dividends themselves. Substituting (A.8) and (A.11) into the Euler equation and applying the same linearization arguments as in Proposition 4 yields

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} \approx \sum_{k=1}^{K} \lambda_{k,t} g_k(Z_{i,t}) + \sum_{k,\ell=1}^{K} \lambda_{k\ell,t} \tilde{g}_{k\ell}(Z_{i,t}), \quad \text{(A.12)}$$

for suitable factor prices of risk $\lambda_{k,t}, \lambda_{k\ell,t}$ and exposure functions $\tilde{g}_{k\ell}(Z_{i,t})$ associated with the quadratic factor terms. Under conditional normality of the primitive factors, the centered quadratic terms are orthogonal to the linear factors and their contribution vanishes, reducing (A.12) to the linear multi-factor pricing equation used in the main text. Expression (A.12) is the natural

multi-factor generalization of (4.5): each physical, policy, or technology factor is associated with a priced characteristic given by its exposure function in the dividend and damage processes, while the quadratic combinations reflect higher-order interactions induced by the dependence of the stochastic discount factor on nonlinear climate damages.

The key observation is that neither the presence of nonlinear damages nor the presence of multiple factors alters the basic structure of our earlier results: to leading order, expected excess returns are linear in a vector of exposure coefficients $(g_1(Z_{i,t}), \ldots, g_K(Z_{i,t}), \tilde{g}_{k\ell}(Z_{i,t}))$, and these coefficients are model-specific functions of firm characteristics $Z_{i,t}$. In particular, if policy shocks enter cash flows through a term of the form $-\tau_{t+1}X_{i,t}$, the corresponding exposure function is naturally $g_k(Z_{i,t}) = -X_{i,t}$, even in the presence of additional physical or technology factors. Conversely, if physical shocks enter via damages that are nonlinear in $\bar{X}_t$ and $f_{k,t+1}$, the resulting priced characteristics will typically involve nonlinear functions of emissions and other firm attributes. In neither case is there a general reason for the emission intensity $X_{i,t}/V_{i,t}$ to emerge as a unique sufficient statistic for premia. The qualitative conclusions of Sections 3.4 and 4 are therefore robust to quadratic damages and to multiple climate shocks: the priced objects are exposure functions $g_k(Z_{i,t})$ determined by technology, policy, and preferences, and these need not collapse to a single ratio such as $X_{i,t}/V_{i,t}$.

B CRRA preferences and incomplete markets

This appendix shows that the main pricing structure derived in the CARA-normal benchmark carries over, in local approximation, to an economy with CRRA preferences and incomplete markets. The key difference is that the aggregate price of climate risk is now governed by wealth-weighted (or, more precisely, consumption-weighted) risk tolerance rather than by the sum of inverse CARA coefficients. Throughout, it is useful to keep the distinction between a *price* (dollar) equation and a *return* equation: the primitive exposure is level-based in dividends, while expected returns load on the value-normalized exposure.

B.1 Setup

Time is $t = 0, 1$. Uncertainty is driven by a scalar climate shock ζ with

$$\mathbb{E}[\zeta] = 0, \qquad \mathrm{Var}(\zeta) = \sigma_\zeta^2 \in (0, \infty),$$

and all random variables are jointly normally distributed conditional on date-0 information.

There are N firms indexed by $i = 1, \ldots, N$ and H households indexed by $h = 1, \ldots, H$. Each firm has one share outstanding, so market clearing requires $\sum_{h=1}^{H} \theta_i^h = 1$ for all i. Firm i has a fixed level of emissions $X_i \geq 0$ and a date-1 dividend given by

$$D_i = \mu_i + \eta X_i \zeta, \tag{B.1}$$

where $\mu_i \in \mathbb{R}$ is a deterministic component and $\eta > 0$ is a technology parameter common across firms. Aggregate emissions are

$$\bar{X} \equiv \sum_{i=1}^{N} X_i.$$

Climate damages at date 1 are

$$\Gamma(\zeta) = \kappa \bar{X} \zeta, \qquad \kappa > 0. \tag{B.2}$$

The scalar ζ is therefore interpreted as a shock to the per-unit cost or value of emissions, in the reduced-form sense discussed in the main text.

Household h has date-0 wealth $W_0^h > 0$ and trades the N stocks and a risk-free asset with gross return $R_f > 0$. Let V_i denote the date-0 price of stock i, and let θ_i^h denote the number of shares of stock i held by household h. Let b^h denote the holding of the risk-free asset. The budget constraint at $t = 0$ is

$$\sum_{i=1}^{N} V_i \theta_i^h + \frac{1}{R_f} b^h = W_0^h. \tag{B.3}$$

Date–1 consumption of household h is

$$C_1^h(\zeta) = b^h R_f + \sum_{i=1}^{N} \theta_i^h D_i(\zeta). \tag{B.4}$$

Household h experiences disutility from climate damages with intensity $\phi_h \geq 0$ and has CRRA preferences over climate-adjusted consumption:

$$U^h = \mathbb{E}\left[u_h\big(C_1^h - \phi_h \Gamma(\zeta)\big)\right], \qquad u_h(x) = \frac{x^{1-\gamma_h}}{1-\gamma_h}, \quad \gamma_h > 0. \tag{B.5}$$

Preferences are thus heterogeneous in risk aversion γ_h and climate concern ϕ_h. Damages are not tradable, so markets are incomplete: the non-pecuniary climate risk cannot be fully hedged with

traded assets.

We focus on equilibria in which the shocks are small relative to the level of climate-adjusted consumption for each household. This allows for a local mean-variance approximation of expected utility around a deterministic reference point.

B.2 Local mean-variance approximation under CRRA

Define climate-adjusted consumption of household h as

$$Y_h(\zeta) \equiv C_1^h(\zeta) - \phi_h \Gamma(\zeta). \tag{B.6}$$

Using (B.1), (B.2), and (B.4), we can write

$$\begin{aligned} Y_h(\zeta) &= b^h R_f + \sum_{i=1}^{N} \theta_i^h \mu_i + \left(\sum_{i=1}^{N} \theta_i^h \eta X_i - \phi_h \kappa \bar{X} \right) \zeta \\ &= A_h + B_h \zeta, \end{aligned} \tag{B.7}$$

where

$$A_h \equiv b^h R_f + \sum_{i=1}^{N} \theta_i^h \mu_i, \qquad B_h \equiv \sum_{i=1}^{N} \theta_i^h \eta X_i - \phi_h \kappa \bar{X}.$$

Let $\bar{Y}_h \equiv \mathbb{E}[Y_h] = A_h$ denote the conditional mean of Y_h. For the local approximation we assume that the stochastic component $B_h \zeta$ is small relative to $\bar{Y}_h$. A second-order Taylor expansion of $u_h(\cdot)$ around $\bar{Y}_h$ yields

$$u_h(Y_h) \approx u_h(\bar{Y}_h) + u_h'(\bar{Y}_h)(Y_h - \bar{Y}_h) + \frac{1}{2} u_h''(\bar{Y}_h)(Y_h - \bar{Y}_h)^2.$$

Taking expectations and choosing the expansion point $\bar{Y}_h \equiv \mathbb{E}[Y_h]$ implies

$$\mathbb{E}[u_h(Y_h)] \approx u_h(\bar{Y}_h) + \frac{1}{2} u_h''(\bar{Y}_h) \mathrm{Var}(Y_h).$$

Since $\mathrm{Var}(Y_h) = B_h^2 \sigma_\zeta^2$, expected utility is approximately

$$\mathbb{E}[u_h(Y_h)] \approx u_h(\bar{Y}_h) + \frac{1}{2} u_h''(\bar{Y}_h) B_h^2 \sigma_\zeta^2.$$

Define the local absolute risk aversion of household h at $\bar{Y}_h$ by

$$\tilde{\alpha}_h \equiv -\frac{u_h''(\bar{Y}_h)}{u_h'(\bar{Y}_h)}. \tag{B.8}$$

Thus, under CRRA preferences, the local approximation maps the household's problem into a mean-variance objective with a state-dependent (local) coefficient of absolute risk aversion.

For CRRA utility,

$$u_h'(x) = x^{-\gamma_h}, \qquad u_h''(x) = -\gamma_h x^{-\gamma_h - 1},$$

so

$$\tilde{\alpha}_h = \frac{\gamma_h}{\bar{Y}_h}. \tag{B.9}$$

Dividing the approximation for $\mathbb{E}[u_h(Y_h)]$ by $u_h'(\bar{Y}_h) > 0$ yields the equivalent objective

$$\mathbb{E}[Y_h] - \frac{\tilde{\alpha}_h}{2}\mathrm{Var}(Y_h) = A_h - \frac{\tilde{\alpha}_h}{2} B_h^2 \sigma_\zeta^2. \tag{B.10}$$

The constant terms are irrelevant for portfolio choice. Using $Y_h = C_1^h - \phi_h \Gamma(\zeta)$ and $\mathbb{E}[\zeta] = 0$, maximizing (B.10) is thus equivalent, in the local approximation, to maximizing

$$\mathbb{E}[C_1^h - \phi_h \Gamma(\zeta)] - \frac{\tilde{\alpha}_h}{2}\mathrm{Var}[C_1^h - \phi_h \Gamma(\zeta)]. \tag{B.11}$$

Expression (B.11) has the same form as the CARA-normal mean-variance objective in the main text, with the constant absolute risk aversion coefficient α_h replaced by the local coefficient $\tilde{\alpha}_h = \gamma_h / \bar{Y}_h$.

B.3 First-order conditions and equilibrium price of climate risk

Under the local mean-variance objective (B.11), household h chooses $\{\theta_i^h\}_{i=1}^N$ to maximize

$$\sum_{i=1}^N \theta_i^h (\mu_i - V_i R_f) - \frac{\tilde{\alpha}_h}{2} \sigma_\zeta^2 \delta_h^2,$$

where

$$\delta_h \equiv \sum_{j=1}^N \theta_j^h \eta X_j - \phi_h \kappa \bar{X}. \tag{B.12}$$

The first-order condition with respect to θ_i^h is

$$\mu_i - V_i R_f - \tilde{\alpha}_h \sigma_\zeta^2 \delta_h \eta X_i = 0, \qquad i = 1, \ldots, N. \tag{B.13}$$

The left-hand side of (B.13) does not depend on h, so equilibrium requires that the product $\tilde{\alpha}_h \sigma_\zeta^2 \delta_h$ coincide across all households h that hold stock i. Hence there exists a scalar λ such that

$$\mu_i - V_i R_f = \lambda \eta X_i, \qquad \delta_h = \frac{\lambda}{\tilde{\alpha}_h \sigma_\zeta^2}. \tag{B.14}$$

Equation (B.14) is the *price* (dollar) risk-premium relation. Dividing both sides by V_i and using $\mathbb{E}[R_i] = \mathbb{E}[D_i]/V_i$ yields the corresponding *return* representation,

$$\mathbb{E}[R_i] - R_f = \lambda \eta \frac{X_i}{V_i}. \tag{B.15}$$

Thus, as in the CARA benchmark, emission *levels* X_i govern the primitive cash-flow exposure in dividends, while expected *returns* load on the exposure X_i/V_i.

To solve for λ, multiply the definition of δ_h in (B.12) by η and sum over h:

$$\sum_{h=1}^{H} \sum_{j=1}^{N} \theta_j^h \eta^2 X_j - \kappa \bar{X} \eta \sum_{h=1}^{H} \phi_h = \eta \sum_{h=1}^{H} \delta_h. \tag{B.16}$$

Using market clearing $\sum_{h=1}^{H} \theta_j^h = 1$ for each j, the left-hand side becomes

$$\sum_{j=1}^{N} \eta^2 X_j - \kappa \bar{X} \eta \sum_{h=1}^{H} \phi_h = \eta^2 \bar{X} - \kappa \bar{X} \eta \sum_{h=1}^{H} \phi_h.$$

The right-hand side of (B.16), using (B.14), is

$$\eta \sum_{h=1}^{H} \delta_h = \eta \sum_{h=1}^{H} \frac{\lambda}{\tilde{\alpha}_h \sigma_\zeta^2} = \frac{\eta \lambda}{\sigma_\zeta^2} \sum_{h=1}^{H} \frac{1}{\tilde{\alpha}_h}.$$

Equating both sides and dividing by η yields

$$\eta \bar{X} - \kappa \bar{X} \sum_{h=1}^{H} \phi_h = \frac{\lambda}{\sigma_\zeta^2} \sum_{h=1}^{H} \frac{1}{\tilde{\alpha}_h}.$$

Solving for λ gives the CRRA counterpart to Proposition 2.

Proposition A.1 (Price of climate risk under CRRA)**.** *Under the assumptions of this appendix, in a competitive equilibrium with CRRA preferences and incomplete markets, the equilibrium price*

of climate risk is

$$\lambda = \frac{\sigma_\zeta^2 \bar{X}}{\sum_{h=1}^{H} \frac{1}{\tilde{\alpha}_h}} \Big(\eta - \kappa \sum_{h=1}^{H} \phi_h\Big), \qquad \tilde{\alpha}_h = \frac{\gamma_h}{\bar{Y}_h}. \tag{B.17}$$

Accordingly, expected excess returns satisfy the return representation (B.15)*,*

$$\mathbb{E}[R_i] - R_f = \lambda \eta \frac{X_i}{V_i},$$

and the corresponding price (dollar) relation in (B.14) *can be written equivalently as*

$$\mathbb{E}[D_i] - V_i R_f = \lambda \eta X_i.$$

The denominator in (B.17) can be written as

$$\sum_{h=1}^{H} \frac{1}{\tilde{\alpha}_h} = \sum_{h=1}^{H} \frac{\bar{Y}_h}{\gamma_h},$$

which is the sum of local risk tolerances $\bar{Y}_h/\gamma_h$. Thus, relative to the CARA case, the price of climate risk is governed by aggregate risk tolerance rather than by $\sum_h 1/\alpha_h$. The term in parentheses, $(\eta - \kappa \sum_h \phi_h)$, is unchanged: as in the CARA benchmark, greater aggregate climate concern $\sum_h \phi_h$ reduces, and can in principle overturn, the purely financial component of the brown premium.

B.4 Discussion and relation to the CARA benchmark

Proposition A.1 shows that, in a CRRA-incomplete-markets setting, the local linear *price* relation

$$\mathbb{E}[D_i] - V_i R_f = \lambda \eta X_i$$

continues to hold, with a price of climate risk λ given by (B.17). The structure is identical to the CARA-normal benchmark: the primitive cash-flow exposure is proportional to the emission level X_i, the numerator scales with $\sigma_\zeta^2 \bar{X}$, and the aggregate climate concern $\sum_h \phi_h$ enters linearly in the term $(\eta - \kappa \sum_h \phi_h)$. The only change is that the denominator is the sum of local risk tolerances, $\sum_h \bar{Y}_h/\gamma_h$, rather than the sum of inverse CARA coefficients.

Translating this into a statement about *returns* requires dividing by the asset price: from the

price relation one obtains

$$\mathbb{E}[R_i] - R_f = \frac{\mathbb{E}[D_i] - V_i R_f}{V_i} = \lambda\eta \frac{X_i}{V_i}.$$

Under the local approximation, the economic interpretation of the incomplete-markets equilibrium is unchanged. Heterogeneous risk aversion and climate concern, combined with unhedgeable climate damages, generate a nontrivial price of climate risk λ and a one-factor representation in which the primitive exposure is level-based in dividends while return premia load on the value-normalized exposure. The CARA and CRRA formulations therefore lead to qualitatively identical asset-pricing implications within the class of small-shock, linear-exposure environments considered in the main text.

C Welfare Losses from Market Incompleteness

This appendix provides the formal derivation of the welfare-loss measure summarized in Section **??**. The purpose is to make precise how welfare comparisons are conducted in the presence of incomplete markets and heterogeneous climate concern, and to clarify the sense in which equilibrium carbon premia differ from planner implementation wedges. As emphasized in the main text, the analysis here is not intended to map observed carbon premia into a social cost of carbon, but rather to characterize the allocation-level efficiency cost that arises when climate risk is imperfectly shared.

C.1 Planner welfare benchmark

Let $W(\cdot)$ denote the planner welfare functional introduced in Section 7.4. For any feasible aggregate allocation (C_0, C_1, X_1),

$$W(C_0, C_1, X_1) \;\equiv\; u(C_0) + \beta\big(u(C_1) - d(X_1)\big),$$

where $d(X_1)$ denotes aggregate climate damages. Let $(C_0^{FB}, C_1^{FB}, X_1^{FB})$ denote the first-best allocation that solves the planner's problem under complete markets, and define

$$W^{FB} \;\equiv\; W(C_0^{FB}, C_1^{FB}, X_1^{FB}).$$

C.2 Incomplete-markets allocation

Let $(C_0^{IM}, C_1^{IM}, X_1^{IM})$ denote the aggregate allocation induced by the competitive equilibrium in the incomplete-markets economy described in Section 3, with the same technology, damage function, and shock distribution as in the planner benchmark. The planner evaluation of this second-best allocation is

$$W^{IM} \equiv W(C_0^{IM}, C_1^{IM}, X_1^{IM}).$$

Because climate damages are unspanned and households differ in climate concern, the allocation $(C_0^{IM}, C_1^{IM}, X_1^{IM})$ generally does not satisfy the planner's first-order conditions, even though asset prices in equilibrium reflect well-defined carbon premia.

C.3 Consumption-equivalent welfare loss

The welfare loss from market incompleteness is defined in consumption-equivalent units. Specifically, let $\Delta c_1 \geq 0$ denote the unique scalar (on the relevant domain) that satisfies

$$u(C_0^{FB}) + \beta\big(u(C_1^{FB} - \Delta c_1) - d(X_1^{FB})\big) = W^{IM}.$$

The quantity Δc_1 measures the reduction in date-1 consumption that makes the planner indifferent between the first-best allocation and the incomplete-markets allocation.

For reporting purposes, we also express the welfare loss as a fraction of first-best date-1 consumption,

$$\Delta W \equiv \frac{\Delta c_1}{C_1^{FB}}.$$

C.4 Interpretation and decomposition

The welfare loss ΔW captures two distinct channels. First, incomplete markets prevent full insurance against aggregate climate risk, leading to inefficient consumption smoothing relative to the planner benchmark even in the absence of preference heterogeneity. Second, heterogeneity in climate concern implies that the equilibrium stochastic discount factor reflects a wealth-weighted aggregation of private marginal rates of substitution rather than the planner's marginal valuation of climate damages. As a result, equilibrium investment and emission choices do not internalize the social cost of carbon.

Importantly, ΔW is an allocation object and need not be monotone in the magnitude of equi-

librium carbon premia. Carbon premia summarize second-best pricing of exposure to climate and policy shocks, whereas ΔW is pinned down by the gap between allocations under complete and incomplete risk sharing evaluated under a common welfare criterion. This distinction clarifies why observed carbon premia should not be interpreted as sufficient statistics for welfare or for optimal climate policy.

D Infinite-horizon production economy

This section embeds the static incomplete-markets structure into a dynamic production economy. The goal is to show formally that, under standard CARA-normal assumptions, the stochastic discount factor (SDF) admits an exponential-affine representation with a climate-shock loading that is directly linked to the cross-section of (α_h, ϕ_h), and that the resulting dynamic pricing relation preserves the emission-based structure derived in the static model.

Technology, capital, and emissions Time is discrete, $t = 0, 1, 2, \ldots$. Each firm $i \in \{1, \ldots, N\}$ chooses capital $K_{i,t}$ and an emission scale $q_{i,t}$ at each date t. Output at t is given by

$$Y_{i,t} = F_i(K_{i,t}, q_{i,t}) - \Psi_i(q_{i,t}), \tag{D.1}$$

where $F_i : \mathbb{R}^2_+ \to \mathbb{R}_+$ is strictly concave and twice continuously differentiable, and $\Psi_i : \mathbb{R}_+ \to \mathbb{R}_+$ is convex.

Emissions of firm i at date t are

$$X_{i,t} = \chi_i q_{i,t}, \qquad \chi_i > 0, \tag{D.2}$$

so that aggregate emissions are $\bar{X}_t = \sum_{i=1}^N X_{i,t}$. Capital evolves according to

$$K_{i,t+1} = (1 - \delta_i)K_{i,t} + I_{i,t}, \qquad \delta_i \in (0, 1). \tag{D.3}$$

Climate risk and dividends Let $\{\zeta_t\}_{t \geq 1}$ be an i.i.d. climate or policy shock with $\mathbb{E}[\zeta_{t+1}|\mathcal{F}_t] = 0$ and $\mathrm{Var}[\zeta_{t+1}|\mathcal{F}_t] = \sigma^2_\zeta$. Climate damages at $t + 1$ are

$$\Gamma_{t+1} = \kappa \bar{X}_t \zeta_{t+1}, \qquad \kappa > 0. \tag{D.4}$$

Firm i's dividend at date $t+1$, conditional on decisions at time t, is

$$D_{i,t+1} = F_i(K_{i,t+1}, q_{i,t}) - \Psi_i(q_{i,t}) - I_{i,t+1} + \eta X_{i,t}\zeta_{t+1} + \tilde{\varepsilon}_{i,t+1}. \tag{D.5}$$

where $\tilde{\varepsilon}_{i,t+1}$ is idiosyncratic. As in the static model, the primitive cash-flow exposure to climate risk is proportional to the *level* of emissions chosen in the previous period, $X_{i,t}$, consistent with a one-period implementation lag.

Households, incomplete markets, and dynamic mean–variance representation There are H households indexed by h. Household h has preferences

$$U^h = \mathbb{E}\left[\sum_{t=0}^{\infty} \beta^t u^h(C_{h,t} - \phi_h \Gamma_t)\right], \qquad u^h(x) = -\exp(-\alpha_h x), \tag{D.6}$$

with heterogeneity in (α_h, ϕ_h). Climate damages Γ_t are not traded, so markets are incomplete.

Define climate-adjusted consumption

$$\tilde{C}_{h,t} = C_{h,t} - \phi_h \Gamma_t.$$

Under CARA utility and joint conditional normality, the household's dynamic problem reduces at each date t to

$$\max \ \mathbb{E}_t[\tilde{C}_{h,t+1}] - \frac{\alpha_h}{2}\mathrm{Var}_t(\tilde{C}_{h,t+1}), \tag{D.7}$$

which is the exact dynamic analogue of the static mean-variance problem.

Aggregate stochastic discount factor and its climate loading Let $\theta^h_{i,t}$ denote household h's holdings of firm i at date t. Using (D.4)-(D.5), the innovation to climate-adjusted consumption can be written as

$$\tilde{C}_{h,t+1} - \mathbb{E}_t[\tilde{C}_{h,t+1}] = \Big(\sum_{i=1}^{N} \theta^h_{i,t}\eta X_{i,t} - \phi_h \kappa \bar{X}_t\Big)\zeta_{t+1} + \tilde{\varepsilon}_{h,t+1}. \tag{D.8}$$

Using the mean-variance representation (D.7), optimal portfolio choice implies that expected excess returns satisfy

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \alpha_h \,\mathrm{Cov}_t(R_{i,t+1}, \tilde{C}_{h,t+1}).$$

Substituting (D.5) and (D.8) yields

$$\mathbb{E}_t[D_{i,t+1}] - (1 + R_{f,t})V_{i,t} = \alpha_h \sigma_\zeta^2 \delta_{h,t} \eta X_{i,t}, \qquad \delta_{h,t} = \sum_{j=1}^{N} \theta_{j,t}^h \eta X_{j,t} - \phi_h \kappa \bar{X}_t. \tag{D.9}$$

Since the left-hand side does not depend on h, market clearing implies the existence of a scalar λ_t such that

$$\lambda_t = \frac{\sigma_\zeta^2 \bar{X}_t}{\sum_{h=1}^{H} 1/\alpha_h} \Big(\eta - \kappa \sum_{h=1}^{H} \phi_h\Big). \tag{D.10}$$

SDF representation and pricing implications The aggregate SDF between t and $t+1$ admits the exponential-affine form

$$m_{t+1} = M_t \exp(-B_t \zeta_{t+1}), \tag{D.11}$$

with $\mathbb{E}_t[m_{t+1}] = 1/(1 + R_{f,t})$. A factor representation to the Euler equation implies the payoff risk-premium relation

$$\mathbb{E}_t[D_{i,t+1}] - (1 + R_{f,t})V_{i,t} = B_t \sigma_\zeta^2 \eta X_{i,t}. \tag{D.12}$$

Comparing (D.12) with (D.9) and using (D.10) identifies the SDF loading,

$$B_t = \frac{\lambda_t}{\sigma_\zeta^2} = \frac{\bar{X}_t}{\sum_{h=1}^{H} 1/\alpha_h} \Big(\eta - \kappa \sum_{h=1}^{H} \phi_h\Big). \tag{D.13}$$

Dividing (D.12) by firm value yields the expected excess return,

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = B_t \sigma_\zeta^2 \eta \frac{X_{i,t}}{V_{i,t}}. \tag{D.14}$$

The pricing kernel loading B_t summarizes the aggregate price of climate risk. Although B_t is common across firms, equilibrium emissions $X_{i,t}$ and firm values $V_{i,t}$ are jointly determined by firm-specific technologies, capital stocks, and adjustment costs. Consequently, comparisons based solely on contemporaneous emission intensity $X_{i,t}/V_{i,t}$ need not preserve the ranking of firms by equilibrium exposure to climate risk once emission policies are endogenous and firm values reflect continuation payoffs under optimal adjustment.

Dynamic asset pricing relation Combining (D.14) and (D.13) yields

$$\mathbb{E}_t[R_{i,t+1}] - R_{f,t} = \lambda_{X,t} \frac{X_{i,t}}{V_{i,t}}, \qquad \lambda_{X,t} \equiv \lambda_t \eta. \tag{D.15}$$

Equation (D.15) implies that, conditional on equilibrium objects at date t, expected returns

are proportional to emission intensity $X_{i,t}/V_{i,t}$. In this reduced-form sense, intensity summarizes cross-sectional differences in expected returns within a given equilibrium. However, this does not imply that emission intensity is a primitive or structurally sufficient statistic for climate exposure. The underlying cash-flow exposure is proportional to emission levels $X_{i,t}$, while firm value $V_{i,t}$ reflects continuation values that depend on capital stocks, adjustment costs, and expectations of future policy. Because these state variables differ across firms with identical intensity, the mapping from primitives to equilibrium exposure need not be homogeneous of degree one in $(X_{i,t}, V_{i,t})$. Intensity therefore emerges as a reduced-form normalization of equilibrium exposure rather than a primitive sufficient statistic determined by technology. This distinction underlies Proposition 3, which characterizes the knife-edge conditions under which intensity is structurally sufficient.

The primitive cash-flow exposure in dividends is proportional to emission levels $X_{i,t}$, while expected returns load on the corresponding value-normalized exposure $X_{i,t}/V_{i,t}$. To relate the dynamic pricing relation to Proposition 3, note that equation (D.15) can be written in the one-factor form $\mathbb{E}_t[R_{i,t+1} - R_{f,t}] = \lambda_t \, g(Z_{i,t})/V_{i,t}$ with a reduced-form exposure $g(Z_{i,t})$ proportional to emissions $X_{i,t}$. However, in the dynamic economy, $g(Z_{i,t})$ reflects firms' equilibrium emission policies, which respond endogenously to the climate shock through optimal investment and adjustment decisions. These responses depend on firm-specific state variables and are therefore not scale-invariant across firms with the same emission intensity. As a result, emission intensity $X_{i,t}/V_{i,t}$ fails to be a sufficient statistic for expected excess returns, despite the apparent one-factor representation.

Firms' dynamic investment and emission choices Let $V_{i,t}$ denote the ex-dividend market value of firm i at date t. Shareholders value the stream of dividends using the aggregate stochastic discount factor:

$$V_{i,t} = \mathbb{E}_t \left[\sum_{s=t+1}^{\infty} \left(\prod_{u=t+1}^{s} m_u \right) D_{i,s} \right]. \tag{D.16}$$

Capital evolves according to D.3 where investment $I_{i,t}$ is chosen at date t and paid immediately. Dividends at date t are given by

$$D_{i,t} = F_i(K_{i,t}, q_{i,t}) - \Psi_i(q_{i,t}) - I_{i,t} + \eta X_{i,t-1} \zeta_t + \tilde{\varepsilon}_{i,t}. \tag{D.17}$$

Firm i chooses sequences $\{K_{i,t+1}, q_{i,t}\}_{t \geq 0}$ to maximize $V_{i,0}$, taking prices and the SDF process

$\{m_{t+1}\}$ as given. The Bellman equation is therefore

$$V_{i,t} = \max_{K_{i,t+1},\, q_{i,t}} \{D_{i,t} + \mathbb{E}_t[m_{t+1} V_{i,t+1}]\}. \tag{D.18}$$

We assume that investment and emission choices made at date t affect production, emissions, and dividends realized at date $t+1$ through the capital law of motion (D.3). This one-period implementation lag ensures that the firm's control variables enter next-period cash flows and therefore the Euler equation determining equilibrium asset prices.

The first-order condition with respect to the emission scale $q_{i,t}$ is

$$\mathbb{E}_t\left[m_{t+1}\frac{\partial D_{i,t+1}}{\partial q_{i,t}}\right] + \mathbb{E}_t\left[m_{t+1}\frac{\partial V_{i,t+1}}{\partial q_{i,t}}\right] = 0. \tag{D.19}$$

Under the maintained assumption that $q_{i,t}$ affects future firm value only through next-period dividends, the second term in (D.19) vanishes. Because capital evolves according to (D.3) and does not depend on $q_{i,t}$, emission choices affect continuation value only through dividends realized at $t+1$. Using (D.5), the first-order condition simplifies to

$$\mathbb{E}_t\left[m_{t+1}\left(\frac{\partial F_i(K_{i,t+1}, q_{i,t})}{\partial q_{i,t}} - \Psi_i'(q_{i,t}) + \eta\chi_i\zeta_{t+1}\right)\right] = 0. \tag{D.20}$$

Using (D.11) and normality of ζ_{t+1},

$$\mathbb{E}_t[m_{t+1}\zeta_{t+1}] = -B_t\sigma_\zeta^2\,\mathbb{E}_t[m_{t+1}],$$

so that (D.20) can be written as

$$\mathbb{E}_t[m_{t+1}]\left(\frac{\partial F_i(K_{i,t+1}, q_{i,t})}{\partial q_{i,t}} - \Psi_i'(q_{i,t}) - \eta\chi_i B_t\sigma_\zeta^2\right) = 0. \tag{D.21}$$

Dividing by $\mathbb{E}_t[m_{t+1}]$ and using $B_t = \lambda_t/\sigma_\zeta^2$ yields

$$\frac{\partial F_i(K_{i,t+1}, q_{i,t})}{\partial q_{i,t}} - \Psi_i'(q_{i,t}) = \eta\chi_i\lambda_t. \tag{D.22}$$

Equation (D.22) shows that firms equate marginal private benefits of emissions to a climate-risk pricing wedge governed by the same equilibrium price of risk λ_t that prices returns in (D.15). In contrast to a representative-agent benchmark, this wedge reflects equilibrium asset pricing under

incomplete markets rather than a planner's Pigouvian tax based on emission intensity (violating Proposition 3 (ii)–(iii)).

Although expected returns admit the reduced-form representation $\mathbb{E}_t[R_{i,t+1} - R_{f,t}] = \eta B_t X_{i,t}/V_{i,t}$, this expression should be interpreted as a pricing relation conditional on equilibrium emission choices. In the dynamic economy, both emissions $X_{i,t}$ and firm values $V_{i,t}$ are endogenous objects determined by optimal investment and adjustment decisions that depend on firm-specific state variables. As a result, the scale-invariance condition required for emission intensity to serve as a robust sufficient statistic becomes dynamically fragile: intensity-based comparisons need not be stable once equilibrium policies and continuation values are taken into account (Proposition 3).
